Chronic pain is a frequent complication after SCI that occurs in up to two-thirds of patients. Pain after SCI may be classified as nociceptive pain from stimulation of nociceptors, or neuropathic pain from damage to the sensory system itself. Most patients will report onset of chronic pain within 6 months after the injury, and frequently whilst still in ICU. Gabapentinoids (gabapentin and pregabalin) for neuropathic pain have the strongest evidence to support their efficacy.[51] Tricyclic antidepressants such as amitriptyline are effective for neuropathic pain in patients who also have depression. Infusions of opiates, ketamine and lidocaine are effective for neuropathic pain in the short term.[51] Behavioural therapy may be useful in addition to pharmacological treatment. Consultation with a pain specialist should be sought in patients with severe, refractory pain.

GASTROINTESTINAL

Paralytic ileus and acute gastric dilatation are common initially following SCI. The upper motor neuron bowel syndrome is seen following lesions above the cauda equina; it is characterised by increased colonic wall and anal tone with loss of external anal sphincter control, which results in constipation and faecal retention. Defaecation may be induced by a reflex activity caused by a rectal stimulus such as an irritant suppository or digital stimulation. Other components of bowel management programmes include adequate fluid intake, diet, laxatives and, rarely, surgery or electrical stimulation. Daily suppositories are commonly required, with polyethylene glycol-based suppositories having advantages over hydrogenated vegetable-oil-based bisacodyl suppositories. Opioids and other constipating medications should be avoided where possible.[52]

In lower motor neuron bowel syndrome, seen in cauda equina injuries, the external anal sphincter is lax but colonic peristalsis is inhibited leading to both constipation and overflow incontinence.

Unopposed parasympathetic activity results in stomach hyperacidity, necessitating a proton pump inhibitor for ulcer prophylaxis.

URINARY TRACT

Most patients with a NLOI above L1 experience detrusor overactivity associated with sphincter dysynergia.

This results from the upper motor neuron lesion causing overactivity of both detrusor and bladder sphincters. As a result, the detrusor contracts against a closed sphincter, leading to high intravesical pressure, vesicouretheral reflux, high residual volume, incontinence, bladder spasm and an increased risk of urinary tract infections. Most patients with complete cervical SCI will require a suprapubic cystostomy, whereas thoracolumbar injuries may be managed by intermittent self-catheterisation. Bladder spasticity is common and anticholinergic agents like oxybutynin, tolterodine or trospium should be commenced early in the admission to prevent a contracted, low-volume bladder. The anticholinergic side-effects of these agents may be significant. Most patients require a combination of two anticholinergic medications.

Following SCI, there is a marked alteration in calcium homeostasis, with potential hypercalcaemia, hypercalciuria and a significant risk of calcium oxalate nephrolithiasis. A baseline CT of the renal tract should be obtained a couple of months after SCI, and renal calculi and urinary tract infections should be suspected as precipitants of autonomic dysreflexia.

SKIN CARE

Pressure ulcers are common due to immobility and lack of sensation; 10–30% of patients with SCI develop pressure ulcers.[53] They are a source of significant morbidity and are associated with increased hospital length of stay, life-threatening infections, chronic refractory osteomyelitis and autonomic dysreflexia. Skin healing in denervated skin is significantly delayed, so prevention is vital. The incidence of pressure areas may be reduced by:

- daily skin inspection to detect early pressure areas
- prevention of accumulation of moisture
- good bowel and bladder care
- pressure-relieving mattresses
- protocol-based frequent patient repositioning
- optimal nutrition
- patient participation in their skin care programme.

PSYCHOLOGICAL

Prolonged supportive care is necessary for both patients and their families to help them accept and adapt to neurological disability. Depression is common after SCI. Major depression should be differentiated from depressed mood. Healthcare workers may have the tendency to overdiagnose depression and, conversely, depressive symptoms may be misinterpreted as somatic symptoms (e.g. fatigue) following SCI. Since many patients require antidepressants for pain and are also on drugs with anticholinergic effects (e.g. tolterodine, oxybutynin), management of depression is complex and specialist psychiatric consultation should be sought.

RE-ADMISSION TO ICU

Common causes for re-admission to ICU for patients with pre-existing SCI are infections (urinary tract infections, pneumonia), AD, VTE and surgery (commonly after urinary tract procedure for renal stones). Meticulous attention should be given to skin care. All usual medications should be continued if possible. Abrupt withdrawal of baclofen may lower the seizure threshold. The use of succinylcholine may lead to severe hyperkalaemia.

OUTCOMES FOLLOWING SCI

Hospital survival after SCI is now more than 90%, with long-term survival substantially better than 40 years ago. Factors predictive of higher mortality include higher NLOI, complete SCI, older age and presence of co-morbidities.[54] Depending on the individual circumstances, it may be appropriate to have limitations on treatment for elderly patients with complete and high NLOI. Most deaths are now due to respiratory and cardiovascular disease, with a decreasing proportion due to urinary complications.

The neurological outcome post SCI is best prognosticated with an accurate neurological assessment using the AIS. Even during the first 24 hours, a reliable exam is highly predictive of outcome. Complete (ASIA A) injuries have the least potential for recovery, with only 7% converting to ASIA B by 1 year and none becoming motor incomplete. However 54% of ASIA B patients convert to ASIA C or D by 1 year with much better functional outcomes, and nearly all ASIA C under 50 years of age and all ASIA D patients are expected to be ambulatory on discharge from rehabilitation.[15] In the absence of a clinical exam, an MRI may be used to prognosticate but is far less reliable. Most patients improve by one NLOI, with the majority of improvement seen in the first 6 months, but clinically significant strength gains can occur for up to 2 years after injury. Despite significant disability requiring considerable care, functional ability may be surprising to those who manage only the acute phase of SCI. For example, someone with a C5 ASIA A SCI may be able to mobilise with a power wheelchair with hand controls, drive a modified vehicle, and have a family and a rewarding career.

Abdominal and pelvic injuries

Colin McArthur and Pieter HW Lubbert

Although important abdominal injuries are present in only about 20% of hospital trauma admissions,[1] haemorrhage from abdominal and pelvic injuries is the most common cause of preventable trauma death.[2] Most abdominal and pelvic injuries are caused by blunt trauma; penetrating aetiologies can account for up to a quarter of cases, depending on the society concerned.[3] Important considerations with abdominal and pelvic injuries are:

- potential for severe haemorrhage
- difficulties in diagnosing visceral injury
- severity of associated injuries (e.g. chest and head)
- complications, especially sepsis.

MECHANISMS OF INJURY

BLUNT INJURIES

Road crashes account for most abdominal and pelvic blunt injuries. Injuries may also result from falls, assaults and industrial accidents.[3] Associated injuries are frequent, involving the thorax (most common), head and extremities. Seat belts and airbags reduce mortality in motor vehicle crashes (mainly by limiting brain injury), but are associated with more lower body injuries including decelerating trauma to cardiovascular structures such as thoracic aorta.

PENETRATING INJURIES

Stab and gunshot wounds account for most penetrating injuries to the abdomen.

STAB AND LACERATION WOUNDS

Entry sites do not accurately predict the nature of deeper injury. Penetration of the thoracic cavity should be suspected with upper abdominal wounds; conversely, lower chest wounds may involve abdominal structures. Selective management of haemodynamically stable patients using investigation and observation algorithms that accurately predict intra-abdominal injury have superseded mandatory laparotomy in high-volume centres.[4]

GUNSHOT WOUNDS

Injuries depend on missile calibre, and its velocity and trajectory. Intra-abdominal, thoracic and multiple organ injuries and mortality are substantially greater than with stab wounds. Laparotomy should be performed in all cases with haemodynamic instability, peritonitis or a clinically un-evaluable abdomen. A non-operative approach for selected low-risk patients remains controversial.[5]

INITIAL TREATMENT AND INVESTIGATIONS

RESUSCITATION

Ensuring adequacy of airway, ventilation and oxygenation are immediate priorities. However, circulatory resuscitation should not delay surgery for uncontrolled haemorrhage.[6] If rapid surgical haemostasis is provided in penetrating trauma, delaying or limiting fluid resuscitation before surgery improves outcome.[7] 'Damage control resuscitation'[8] combining permissive hypovolaemia/hypotension with a haemostatic fluid regimen may limit bleeding and transfusion, but is controversial in blunt injury (see Haemorrhage and Coagulopathy section below). Pneumatic anti-shock garments provide no benefit.[9]

CLINICAL ASSESSMENT

A full clinical examination (including the back) by experienced clinicians is most important. The mechanism of injury may direct attention to particular anatomical areas.

- Contusions, external wounds and their relationship to underlying viscera are noted.
- Abdominal distension, tenderness and peritonism are sought but auscultation for bowel sounds is not useful.
- The rectum is examined for prostatic position, anal tone, blood or other evidence of injury.
- Gastric aspirate and urine are inspected for blood.

Isolated penetrating injuries present few diagnostic problems, but the decision to explore the abdomen can be difficult. Blunt abdominal trauma is often part of multiple injuries, and is more difficult to diagnose clinically, except when abdominal signs are obvious. Nevertheless, in conscious patients, serial assessments can accurately identify those with significant intra-abdominal pathology. In the presence of impaired

consciousness, intellectual disability or spinal, chest or pelvic injury, clinical assessment is unreliable. Other more visually spectacular injuries may also divert attention from the abdomen. Laparotomy is indicated on clinical grounds when there is evisceration, peritonism, or signs of shock with free abdominal fluid.

In all other situations where clinical examination is inadequate, further investigations must be undertaken.[10]

PLAIN X-RAYS

A chest X-ray (preferably erect) is essential. It may demonstrate free intraperitoneal gas, herniation of abdominal contents through a ruptured diaphragm, or an alternative focus of bleeding. Plain films of the abdomen are of no benefit in blunt injuries; however, they may show presence of foreign bodies in penetrating injuries. An anteroposterior pelvic X-ray (or computed tomography (CT) scan) is indicated for all victims of blunt trauma, except conscious patients with normal pelvis on examination.[11]

INVESTIGATIONS FOR OCCULT ABDOMINAL INJURY

ULTRASONOGRAPHY

Focused abdominal sonography for trauma (FAST) can be performed rapidly in the resuscitation room without compromising ongoing treatment. It requires significant training to achieve acceptable accuracy[12] and, although highly specific, its sensitivity of around 85%[13] is less than that of peritoneal lavage or CT in detecting free intra-abdominal fluid following either blunt[14,15] or penetrating[16] trauma. FAST cannot identify hollow viscus injury or the nature of solid organ injury. FAST may reduce the need for other investigations,[17] but the small but important false-negative rate must be considered in determining its role in abdominal assessment algorithms. A limited transthoracic echocardiogram (LTTE) can assess IVC size (an index of volume status) and ventricular contractility, and detect pericardial fluid.[18]

PERITONEAL LAVAGE

Diagnostic peritoneal lavage (DPL)[19] is indicated to exclude intra-abdominal injuries when other methods of investigation (FAST, CT scan) are not available. DPL detects intraperitoneal injury with up to 98% accuracy,[19] but its high sensitivity can result in a significant non-therapeutic laparotomy rate.

DPL is unjustified when an indication for laparotomy already exists. It is relatively contraindicated in pregnancy, significant obesity and previous abdominal surgery.

Generally accepted criteria for a positive DPL are shown in **Table 79.1**.

Table 79.1 Criteria for positive diagnostic peritoneal lavage

CLINICAL		
Initial aspiration of >10 mL frank blood		
Egress of lavage fluid via chest tube or urinary catheter		
Bile or vegetable material in lavage fluid		
LABORATORY		
	BLUNT INJURY	PENETRATING INJURY
Red cells		
Definite	$>100\times10^9$/L	$>20\times10^9$/L
Indeterminate	$50–100\times10^9$/L	$5–20\times10^9$/L
White cells	$>0.5\times10^9$/L	0.5×10^9/L
Amylase	>20 IU/L	>20 IU/L
Alkaline phosphatase	>10 IU/L	>10 IU/L

COMPUTED TOMOGRAPHY

CT requires a still patient, a high-resolution scanner and experienced interpretation to match the sensitivity of peritoneal lavage. Imaging from the top of the diaphragm to the symphysis pubis following i.v. contrast is required to fully assess the abdominal cavity. The safety of undertaking CT in acute trauma depends on the degree of cardiorespiratory stability relative to the speed of scanning and access to resuscitation support. CT is particularly indicated for assessing the retroperitoneum and pelvic fractures, and delineating the nature of abdominal injury (thus guiding non-operative management of some solid organ injuries). It may not detect all hollow viscus traumas, but multidetector CT is more specific and sensitive for bowel injury.[20] Enteric contrast may not improve accuracy.[21] Magnetic resonance imaging offers no advantage over CT in evaluating acute abdominal trauma, and poses significant logistical problems.

CHOICE OF INVESTIGATION

- FAST is non-invasive, rapid, and reasonably accurate when used by trained staff. It can screen for haemoperitoneum, but negative studies should be followed by another investigation.[15,16]
- CT is non-invasive, time-consuming, accurate and has a primary role in defining the location and magnitude of intra-abdominal injuries in stable patients with blunt trauma or penetrating trauma to the flank or back.

FAST and CT are complementary and ideally both should be available. If CT is unavailable, a negative FAST should be followed by either a DPL or a delayed repeat FAST[22] in the patient with blunt trauma in whom clinical examination is inadequate.

LAPAROSCOPY

Diagnostic laparoscopy may be useful in the haemodynamically stable patient. It is good at visualising the diaphragm and identifying a need for laparotomy, but may miss specific organ injuries in blunt abdominal injuries, particularly of the bowel. Laparoscopy appears best suited for the evaluation of equivocal penetrating wounds.[5]

ANGIOGRAPHY

Selective angiography and embolisation are valuable in detecting and treating the source of major haemorrhage from surgically difficult-to-access pelvic and retroperitoneal structures. In selected patients embolisation can also treat haemorrhage from liver and splenic injuries. Angiography in unstable patients is best undertaken in a hybrid operating room.

LAPAROTOMY

Laparotomy can be regarded as both therapeutic and diagnostic. Intra-abdominal injury may be detected by means discussed above, but often only laparotomy can accurately diagnose specific injuries. In severe and multiple trauma, the morbidity of a negative laparotomy is insignificant compared with the dire consequences of not diagnosing and treating a serious injury.

Operative treatment of more severe injuries with difficult haemostasis can cause a lethal triad of hypothermia, acidosis and coagulopathy. A 'damage control' laparotomy[23] with control of haemorrhage and contamination, intraperitoneal packing, elective re-exploration and removal of packs 24–48 hours later should be performed.

- Angiography should be considered and may be required for inaccessible arterial bleeding.
- Temporary prosthetic closure may be required to avoid elevated intra-abdominal pressure.
- Survival is better when the decision to terminate the initial procedure is made earlier.

SPECIFIC INJURIES

SPLEEN

The spleen is the organ most frequently injured by blunt trauma. Injuries vary from a small subcapsular haematoma to hilar devascularisation or shattered spleen, but are rarely fatal with good medical care.[24] Diagnosis may be delayed in mild trauma. Fractures of the lower left ribs are a common association. When associated chest or neurological injuries are severe, minor splenic injury may not initially be detected unless further investigation is undertaken. Minor trauma may cause splenic injury when the spleen is enlarged (e.g. from malaria, lymphoma and haemolytic anaemia).

Immediate splenectomy is indicated in patients with splenic avulsion, fragmentation or rupture, extensive hilar injuries, failure of haemostasis, associated peritoneal contamination from gastrointestinal injury or rupture of diseased spleen. However, overwhelming post-splenectomy infection (OPSI) by encapsulated organisms, such as *Pneumococcus*, can occur early or late (even years) after splenectomy in 0–2% of individuals. It is a particular risk following splenectomy in children and young adults. Polyvalent pneumococcal vaccine should be administered following splenectomy together with vaccination for *Meningococcus* and *Haemophilus influenzae*.[25]

If associated abdominal injuries have been excluded, a non-operative approach can give splenic salvage rates of over 80%. Arterial embolisation can further reduce the need for laparotomy. Failure rates are higher with more severe injuries.[26]

Other treatment alternatives include operative procedures to conserve splenic tissue (e.g. topical haemostatic agents, suture repair, absorbable mesh, partial splenectomy and splenic artery ligation). Benefits of splenectomy with autotransplantation of splenic tissue are unproven.

LIVER

The liver is the second most commonly injured organ after blunt abdominal trauma, and has been the most frequently missed injury in deaths from trauma.[2] Diagnosis is made by laparotomy in unstable patients, or CT in stable patients. Injuries range from small subcapsular haematomas to major parenchymal disruption and laceration of hepatic veins or even hepatic avulsion.

CT assessment enables most patients to be managed without operation. Patients should be haemodynamically stable, have associated major abdominal injuries excluded, and be assessed repeatedly. Follow-up CT scans can show the resolution of injury, which typically takes 2–3 months. CT-guided percutaneous drainage, ERCP and angioembolisation can treat the complications of a non-operative approach such as bile leak, haemobilia, necrosis, abscess and delayed haemorrhage.

If surgery is required, early determination of indications for a damage control approach is important. Perihepatic packing gives best haemostasis. Angiography may identify and treat uncontrolled arterial bleeding. Early complications of liver injury relate to the effects of hypoperfusion or massive blood transfusion. Late complications are usually associated with sepsis.[27]

GASTROINTESTINAL TRACT (GIT)

Injury to the GIT is more common following penetrating than blunt trauma. The very high likelihood of bowel injury in abdominal gunshot wounds should mandate laparotomy. Laparoscopy can be used to

identify those with stab wounds for laparotomy when peritoneal violation cannot be excluded. Posterior stab wounds may damage retroperitoneal structures. CT examination with contrast enema may identify colonic injury better than clinical assessment.[5]

Blunt abdominal injuries include perforation or devascularisation of stomach, duodenum, small intestine, colon and their mesenteries, all of which are difficult to evaluate. Physical signs may be absent initially. FAST may provide a general indication for laparotomy, but is insensitive to bowel injury. CT is a sensitive indicator of free intraperitoneal air, but signs of duodenal perforation or haematoma are subtle even with multidetector CT or enteral contrast. Consequently, duodenal injury may be missed. A high index of suspicion should be maintained in patients with persistent abdominal pain and tenderness.[28]

Bleeding from mesenteric vessels is often self-limiting and may not require surgical control. However, vessel damage can cause ischaemia and infarction, and may require resection of affected bowel. Uncomplicated blunt or penetrating bowel injury can usually be managed by primary repair and anastomosis rather than colostomy.[29] A faecal diversion procedure with delayed repair is indicated in significant peritoneal contamination or severe perineal injury.

PANCREAS

Blunt injuries to the pancreas require considerable force with compression of abdominal contents against the spinal column and are often associated with duodenal, liver and splenic trauma. CT is the most useful initial investigation; however, pancreatic duct injury might be better visualised by MRCP or ERCP. Acute hyperamylasaemia does not predict pancreatic or hollow viscus injury.[30]

Minor injuries require simple drainage and haemostasis. Severe injuries to the body and tail of the pancreas are best managed by distal pancreatectomy. Severe injuries involving the proximal pancreas and duodenum with intact ampulla and common bile duct can be treated by drainage alone if associated duodenal injury is simple to repair. Acute pancreaticoduodenectomy is rarely required; however, it should be considered if there is disruption of the ampullary–biliary–pancreatic union or major devitalisation. Complications such as pancreatitis, fistula, abscess and pseudocyst are common.[31]

KIDNEY AND URINARY TRACT

Blunt injury to the urinary tract is more common than penetrating injury. Identification and treatment of other major injuries often take precedence. Gross haematuria should be investigated; CT is the examination of choice for haemorrhage. Urinary extravasation may be identified only on a repeat scan 10–20 minutes after contrast injection or on a formal retrograde (CT) cystogram. Unless there is unexplained shock, microscopic haematuria does not require further investigation. Renovascular pedicle or ureteric injuries may not cause any haematuria. Most renal injuries resolve with expectant management. Lacerations involving the collecting system or injury to the renal pedicle usually require operative intervention, although restoration of renal function following long warm ischaemic times is unusual. If major renal injury is discovered at emergency laparotomy, intraoperative i.v. urography is an option to ensure contralateral function and identify urinary extravasation. Angio-embolisation may be useful for controlling renal haemorrhage.[32]

Bladder rupture is commonly associated with pelvic fractures. Blunt injury to patients with a distended bladder can cause isolated intraperitoneal bladder rupture. Over 95% of patients have macroscopic haematuria. Retrograde cystography is the investigation of choice because plain abdominal CT has a high false-negative rate. Intraperitoneal bladder rupture requires operative repair and urinary drainage. Patients with sterile urine and extraperitoneal rupture can be managed with catheter drainage alone.[33]

Urethral trauma is caused by direct blunt injury, or occurs in association with pelvic injury. It should be suspected if there is blood at the urinary meatus, perineal injury or abnormal position of the prostate on rectal examination in the male. In the absence of these findings, cautious urethral catheterisation is appropriate. Treatment of urethral trauma is suprapubic drainage and subsequent definitive repair.

DIAPHRAGM

Diaphragmatic injury occurs in fewer than 5% of cases of blunt injury, is left-sided in 80% of cases, and is commonly associated with injuries to abdominal organs. It should also be suspected in penetrating trauma below the fifth rib. Diagnosis can be difficult, especially in the presence of positive-pressure ventilation, and may become evident only after ventilatory support is discontinued. Chest X-rays are commonly abnormal but often with non-specific findings. Laparoscopy and thoracoscopy provide good views of the diaphragm.

Spontaneous healing does not occur, and all defects over 1 cm should be repaired. The risk of associated injuries in acute cases mandates an abdominal approach.[34]

BONY PELVIS AND PERINEUM

Pelvic fractures are primarily caused by vehicular trauma or falls. Associated injuries to the bladder, urethra and intra-abdominal organs are common. Injuries may be life-threatening, initially from major

haemorrhage, and later from sepsis. Significant morbidity can result from damage to pelvic nerves, urethra or the structural integrity of the pelvis. Pelvic injury is suggested by pain on movement, structural instability, gross haematuria or peripelvic ecchymosis. Rectal examination is mandatory to identify rectal injury and prostatic position.

Radiography can confirm bony injury, but CT is usually required to identify associated intra-abdominal injuries (in the haemodynamically stable) and can assist in planning operative stabilisation.

Patients with haemodynamic instability and pelvic fractures must have intra-abdominal haemorrhage excluded. Early FAST is the investigation of choice but has a significant false-negative rate with major pelvic fractures. If grossly positive, laparotomy should precede pelvic interventions. If FAST negative, the risk of life-threatening intra-abdominal haemorrhage is relatively low, and achieving haemostasis for pelvic bleeding becomes the priority; CT and/or laparotomy should follow if the patient is still unstable.[35]

- Temporary pelvic binding (and avoidance of external rotation of the legs) is the preferred emergency measure to improve tamponade by reducing pelvic volume.
- Angiography and selective embolisation is effective in controlling arterial bleeding.[36]
- Retroperitoneal (preperitoneal) packing may reduce the need for angiography.[37]
- External fixation of the pelvis may reduce bleeding near fracture sites and reduce the volume of an open pelvis, but reduced blood loss and improved outcomes are unproven.[35]
- Bleeding from large vessels such as the aorta, common and external iliac arteries, and common femoral artery requires surgical control.

Pelvic fractures range from simple fractures of individual bones requiring bed rest alone to complex fractures. Early operative stabilisation of complex pelvic fractures is preferred in the intensive care unit (ICU), as it facilitates respiratory care, pain control and early mobilisation. Compound pelvic fractures involving the perineum, rectum or vagina require aggressive surgery (which may include diversion of the faecal stream) to avoid high mortality.

RETROPERITONEAL HAEMATOMA

Retroperitoneal haematoma is frequent following blunt trauma, and is commonly caused by injury to the lumbar spine, bony pelvis, bladder or kidney or, less commonly, to the pancreas, duodenum or major vascular structures. Diagnosis may be inferred by excluding other sites of major blood loss, or presumed by signs of underlying organ injury. CT is the most useful investigation in the stable patient.

A central haematoma should be explored with proximal vascular control because of the risk of pancreatic, duodenal or major vascular injury. A lateral or pelvic haematoma should not be explored, unless there is evidence of major arterial injury, intraperitoneal bladder rupture or colonic injury.[38]

TRAUMA IN PREGNANCY

Women injured during pregnancy pose problems of altered physiology, risk to the gravid uterus and fetus, and potential conflict of priorities between mother and fetus, In general, however, the best treatment for the fetus is to treat the mother optimally.

High-flow oxygen must be given until maternal hypoxaemia, hypovolaemia and fetal distress have been excluded:

- Reduced respiratory reserve demands earlier intervention.
- Maternal compensation for blood loss is at the expense of uteroplacental blood flow.
- Pregnant women should be positioned to avoid aortocaval compression.
- Secondary survey must include a vaginal examination and obstetric consultation.
- Upper limbs are preferred for intravenous access.
- Transfusions should be Rhesus compatible.
- All Rhesus-negative mothers should receive immune globulin, because of the immunological risk of even minor fetomaternal haemorrhage.[39]

Only X-rays and CT scans that may significantly alter therapy should be taken (with appropriate shielding), especially in those under 20 weeks' gestation, although examination of body regions outside the abdomen/pelvis offers minimal fetal risk. Ultrasound is the preferred investigation as it is safe and can accurately detect free intra-abdominal fluid, confirm gestation and fetal well-being, and identify placental abnormalities.[40]

CT may miss injuries owing to abdominal crowding. Retroperitoneal haemorrhage is more common in pregnant patients. Placental abruption may conceal significant blood loss. Treatment may be expectant or by caesarean section, depending on the condition of the mother and fetus. Uterine rupture is unusual and will often require hysterectomy. Perimortem caesarean section must commence within 4 minutes of maternal cardiac arrest for best fetal outcome.[40]

Placental abruption, fetal distress and fetal loss are rare following blunt injury, but premature uterine contractions are common. Continuous cardiotocography (indicated at viable gestations) for 6 hours is the most sensitive test to detect obstetric complications.[40] Kleihauer–Betke tests to identify fetomaternal haemorrhage can predict preterm labour[41] and guide additional Rh immune globulin doses.

COMPLICATIONS

HAEMORRHAGE AND COAGULOPATHY

Haemorrhage from abdominal and pelvic injuries is the most common cause of preventable trauma death.[2] Direct tissue injury plus the hypoperfusion of shock causes early acute coagulopathy and hyperfibrinolysis, exacerbated by subsequent haemodilution of clotting factors, hypothermia and acidosis.[42] Disseminated intravascular coagulation occurs infrequently in trauma. Damage control surgery can limit progression to the 'lethal triad' (coagulopathy, hypothermia, acidosis).[23] Low-volume resuscitation ('permissive hypovolaemia/hypotension') for short periods prior to haemostatic intervention is established for penetrating trauma,[7,43] but controversial for blunt injuries due to limited evidence and potential risks to patients with long transport times, cardiovascular disease or central nervous system injury.[44,45] In the absence of such factors, a target systolic pressure of 80–100 mmHg (11–13 kPa) prior to haemostatic intervention may be adequate.[6] Early initiation of a 'massive transfusion protocol', with a high ratio of plasma to packed red cells (typically 1 plasma unit per 1–2 red cells, and often including regular platelets and cryoprecipitate), limits the dilution of asanguineous resuscitation and is effective in minimising acute coagulopathy, and may improve outcome in both blunt and penetrating trauma.[46–48] The combination of limited resuscitation volumes and target blood pressure with a haemostatic transfusion strategy is termed 'damage control resuscitation'.[8] Patient-specific treatment for acute coagulopathy in trauma, including fibrinolysis, may be better guided by point-of-care viscoelastic haemostatic testing (e.g. thromboelastography) than standard laboratory assays.[49,50] The prophylactic administration of the antifibrinolytic tranexamic acid within 3 hours of injury reduced death from bleeding without increasing vascular occlusive events in a large study of patients treated in diverse hospital settings.[51] Its use in advanced trauma care may be best in the pre-hospital environment. Empirical use of recombinant activated factor VII based on number of transfused red cell units is not effective,[52] but still may benefit individual patients with resistant coagulopathy if not significantly hypothermic or acidaemic and if they have adequate fibrinogen.

SEPSIS

Intra-abdominal sepsis remains an important preventable cause of death after trauma. Predisposing factors include:

- peritoneal contamination from GIT injury
- external wounds
- invasive procedures
- delayed diagnosis of hollow viscus injuries
- splenectomy
- devitalised tissue.

Early diagnosis and effective lavage and drainage procedures may reduce the incidence *of* intra-abdominal sepsis. Prophylactic antibiotics for 24 hours are satisfactory for penetrating injuries.[53] Intra-abdominal sepsis should be excluded if unexplained fever and/or neutrophil leucytosis, or multiple organ failure develops. Septic shock may represent a second shock insult to the trauma patient, leading to multiorgan dysfunction. Selective decontamination of the digestive tract may reduce infections in multiple trauma,[54] but its use remains controversial.

GASTROINTESTINAL FAILURE

GIT failure in various forms, ranging from stress ulceration and delayed gastric emptying to paralytic ileus, is a frequent occurrence. Prophylaxis against stress ulceration is indicated in ventilated patients not tolerating gastric feeding.[55] Enteral nutrition is associated with a lower incidence of complications following abdominal trauma.[56] Feeding through a jejunostomy tube placed during surgery or radiologically in the ICU is usually feasible. Parenteral nutrition may be necessary in patients with severe bowel or retroperitoneal injuries.

RAISED INTRA-ABDOMINAL PRESSURE

Although less common than in the past, abdominal distension with raised intra-abdominal pressure may be seen in the critically injured as a consequence of haemorrhage, bowel oedema, ileus or surgical packs. This can have severe adverse effects on respiratory, cardiovascular and renal function.[57] Alleviation is by abdominal decompression and temporary closure,[58] with or without visceral packing. The abdomen is subsequently closed by staged repair as the distension resolves.

VENOUS THROMBOEMBOLISM

Pelvic trauma, postoperative status, higher Injury Severity Score (ISS – see Ch. 3) and underlying medical risk factors increase the risk of venous thromboembolism 1.5 to 3 times greater than trauma patients without such factors.[59] Early initiation of mechanical prophylaxis is usually feasible, and chemoprophylaxis when the risk of injury-associated bleeding has reduced.

Submersion

Cyrus Edibam and Tim Bowles

DEFINITIONS

Drowning has been defined by the World Health Organization in 2002 as follows: 'Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid'.[1] If the victim dies as a result, the event should be referred to as 'fatal drowning', if the drowning process is interrupted, it should be referred to as 'non-fatal drowning'. The Utstein template can be adopted to provide consistent reporting of drowning events and allow accurate categorisation.[2]

EPIDEMIOLOGY

Drowning causes an estimated 400 000 deaths worldwide per year.[3] Of these, 4000 are reported from the USA (approximately 1.5 deaths per 100 000 population) and 290 (1.4 deaths/100 000 population) from Australia.[4,5] Ninety-six per cent of fatal drownings occur in low- or middle-income countries and, worldwide, drowning is the third most common cause of unintentional injury death.[3] In the USA, twice as many non-fatal drownings as fatal ones were recorded in 2009.[4] In Australia, drowning is the leading cause of unintentional injury death in children aged 1 to 3 years.[6] Males predominate, with peaks at 5 and 20 years of age. Private swimming pools and natural water bodies close to home present the greatest risk to young children.[7] Other sites include bath tubs, fish tanks, buckets, toilets and washing machines. Adolescent drowning tends to occur in rivers, lakes, canals and beaches.[8] Lack of adult supervision is almost always to blame for toddler accidents; however, child abuse must also be considered. Alcohol and drug intoxication are associated with up to 40% of adolescent drowning.[9] Other risk factors include epilepsy (18%), trauma (16%) and cardiopulmonary disease (14%).[10] Hyperventilation prior to underwater swimming suppresses the physiological response to rising carbon dioxide tension, allowing hypoxia to ensue with consequent loss of consciousness and water breathing.[11]

PATHOPHYSIOLOGY

Voluntary apnoea and reflex responses occur upon submersion. The *diving response* is characterised by apnoea, marked generalised vasoconstriction and bradycardia in response to cold-water stimulus of the ophthalmic division of the trigeminal nerve. Blood is thus shunted preferentially to the brain and heart. In infants the response may be marked,[12] but only 15% of fully clothed adults show a significant response. Although the diving reflex appears to play a powerful role in oxygen conservation in animals, its role in humans is unknown but may be protective.[13]

After airway immersion, breath holding followed by laryngospasm occurs. This causes progressive hypoxia and hypercarbia, eventually resulting in relaxation of airway reflexes and water aspiration.[11] Up to 22 mL/kg of water has been estimated to be the maximal survivable inhaled water volume.[14] This is followed by a phase of secondary apnoea and loss of consciousness. Hypoxaemic death ensues if the person is not retrieved and resuscitated; acute respiratory distress syndrome (ARDS) occurs in up to 72% of symptomatic survivors.[15] Multiple organ dysfunction and cerebral damage may become evident in those who survive to hospital.

SALT- VERSUS FRESH-WATER ASPIRATION

The differences between salt- and fresh-water drowning have traditionally been emphasised. This is largely on the basis of animal data. In canine models, after aspiration of massive volumes of salt water, it was possible to recover by suction or mechanical drainage greater volumes than were initially instilled.[16] The hypertonic salt water was drawing fluid into the pulmonary interstitial space, which was thought to result in hypovolaemia, hypernatraemia and haemoconcentration as well as pulmonary oedema.

Conversely, after fresh-water aspiration in dogs minimal volumes of fluid were retrievable from the lungs.[17] The hypotonic water was absorbed into the circulation. The pulmonary oedema seen was thought to be secondary to removal of surfactant, and hypervolaemia, dilutional hyponatraemia and haemolysis were expected.

More recent animal data and human case series have demonstrated that the tonicity of the fluid aspirated is not clinically relevant.[18] No clinically detectable difference in the patterns of lung injury is seen between salt- and fresh-water drowning; both types reduce

pulmonary surfactant quantity and function, causing pulmonary oedema and hypoxia by collapse, atelectasis and shunting. Differences in electrolyte disturbance are not generally clinically significant.[14]

WATER CONTAMINANTS

The incidence of pneumonia complicating submersion injury may be greater than 15% in those who survive long enough.[15] Rivers, lakes and coastal waters are greater reservoirs for microbes than well-kept swimming pools. In fresh water, Gram-negative bacteria predominate along with anaerobes and *Staphylococcus* spp., fungi, algal and protozoan species. *Aeromonas* spp. are ubiquitous water-borne bacteria and can be responsible for severe pneumonia.[19] Infection with oral commensals is common, as is infection with multiple organisms. Although prophylactic antibiotic treatment is not recommended in general, if infection is suspected then broad-spectrum antibiotics with antipseudomonal cover is required.[20]

Chemicals in polluted water such as kerosene,[21] chlorine[22] and particulate matter like sand[23] can cause severe pulmonary dysfunction.

TEMPERATURE

Victims of submersion may develop primary or secondary hypothermia. If submersion occurs in icy water (<5°C) hypothermia may develop rapidly and provide some protection against hypoxia. Surface cooling is unlikely to produce adequate protective hypothermia before hypoxia ensues.[13] Most reports of survival after prolonged submersion involve small children in icy water and it has been postulated that protective core cooling occurs rapidly due to cold-water aspiration, ingestion and absorption, though the mechanisms remain controversial.[24]

Of more importance in cold-water submersion are the detrimental 'cold-shock' responses.[25] These responses include a 'gasp' followed by uncontrollable hyperventilation and reduction in maximal breath-hold times, vasoconstriction, tachycardia, hypertension and increased myocardial oxygen consumption. These responses may lead to motor dyscoordination and swimming failure as well as cardiac arrhythmia; hence even strong swimmers may drown quickly in icy waters.

MANAGEMENT

BASIC LIFE SUPPORT

Prompt retrieval from the water is essential, as is immediate on-site resuscitation. As any cardiac arrest is normally secondary to hypoxaemia, five rescue breaths should be administered first, followed by standard basic life support. Compression-only CPR is inappropriate in this case. Rescue breathing can be performed effectively in the water; chest compressions cannot.[18]

The risk of cervical spine injury is small (<0.5%), and attempted cervical spine immobilisation can compromise effective rescue and resuscitation in the water. Therefore, spinal immobilisation is indicated only in the presence of severe injury or consistent history.[18] The Heimlich manoeuvre is no longer recommended in the management of submersion injury as the volume of aspirated water removed at the time of attempt is small and the risk of gastric aspiration is great.[18]

Rewarming should be commenced immediately with the use of blankets and further heat loss should be avoided. When experienced personnel arrive, bag and mask ventilation and advanced cardiac life support are initiated.

INITIAL HOSPITAL MANAGEMENT

Resuscitation continues on arrival to hospital. Endotracheal intubation and mechanical ventilation are instituted if hypoxaemia is severe despite high-flow oxygen or assisted bag and mask respiration. Ventilatory failure, characterised by increasing respiratory distress and rising carbon dioxide levels, and the presence of an impaired conscious level or severe agitation may also necessitate intubation. The stomach should be decompressed by insertion of a nasogastric tube if possible but this may be difficult in a hypoxic agitated patient. Early active rewarming is indicated for severe hypothermia, but hyperthermia should be meticulously avoided.[18]

ASSESSMENT

HISTORY

Attempts should be made to elucidate the time and the duration of submersion, the presence of polluted water and likely contaminants, delay in resuscitation attempts and the likelihood of alcohol ingestion, drug use, pre-existing medical conditions (particularly seizure disorders) and coexisting trauma. If collateral history is available, any symptoms of illness prior to the submersion event should be elicited to rule out or in a medical cause for the drowning that may require treatment.

EXAMINATION

A thorough secondary survey is carried out, concentrating on cardiorespiratory examination in particular, looking for signs of respiratory distress, wheeze, crepitations and peripheral circulatory insufficiency. Neurological status should also be assessed. Clinical deterioration in those with minor symptoms and signs can occur and the patient should be reassessed at frequent intervals.

INVESTIGATIONS

These depend on the clinical circumstances and could include:

- *arterial blood gases/lactate level*
- *plasma biochemistry/serum osmolality:* electrolyte abnormalities are unlikely in sea- or fresh-water drowning. CK should be measured as rhabdomyolysis has been reported[26]
- *haematology:* tests for haemolysis, e.g. total haemoglobin (tHb), free Hb and myoglobin concentrations in the plasma and urine
- *toxicological assays:* for drug and alcohol levels should be considered
- *chest X-ray, 12-lead ECG*
- *microbiology:* tracheal aspirates or sputum for Gram stain, microscopy and culture
- *trauma imaging:* cervical and/or thoracolumbar spine views; CT head and cervical spine if head and neck injury is suspected or the patient is comatose. Imaging of other body areas is dependent upon the clinical likelihood of injury.

ADMISSION CRITERIA

Asymptomatic patients with no clinical findings on cardiorespiratory examination and a normal chest radiograph and blood gas are unlikely to develop ARDS and pneumonia and thus do not require hospital admission.[15,27] All other patients should be admitted to a high-dependency area or intensive care unit for continuous monitoring and rewarming.

RESPIRATORY SUPPORT

Severe agitation or coma mandates intubation and mechanical ventilation; otherwise oxygenation is initially maintained with high-flow oxygen or continuous positive airway pressure (CPAP) by tight-fitting facemask. Superimposed ventilatory failure may be managed with non-invasive bilevel positive airway pressure assistance (BIPAP). The use of bronchodilators may reduce air-flow resistance and the work of breathing if evidence of bronchospasm is present. Given the high frequency of ARDS after drowning, lung-protective strategies should be employed if mechanical ventilation is required. Selective pulmonary vasodilators such as inhaled nitric oxide or inhaled prostacyclin may be useful in severe refractory hypoxaemia. In severe cases, extracorporeal membrane oxygenation has been used in some centres.[28]

CARDIOVASCULAR SUPPORT

Patients with ARDS are often hypovolaemic regardless of the type of water ingestion. Cautious volume expansion and the use of catecholamine infusion may improve cardiac output and blood pressure. Fluid replacement with isotonic fluids is aimed at restoring adequate end-organ perfusion without compromising respiratory function. The use of a central venous or pulmonary artery catheter may be necessary to achieve these goals. In cases where severe circulatory insufficiency or cardiac arrest is associated with severe hypothermia, cardiopulmonary bypass has been used successfully.[29]

CEREBRAL PROTECTION

Better neurological outcome has been demonstrated with induced hypothermia (32–34°C) after cardiac arrest due to ventricular fibrillation.[30] Although no specific data for the cerebral protective effects of hypothermia exist for patients suffering hypoxic brain injury associated with submersion, the data suggest that comatose drowning victims should not be actively rewarmed above 34°C.[18]

No other specific cerebral protective measures have proven efficacy in post anoxic encephalopathy associated with drowning.[31] Maintenance of an adequate cerebral perfusion pressure (mean arterial pressure >90 mmHg (11.97 kPa) in adults, 60–70 mmHg (7.98–9.31 kPa) in children) is the most important goal of therapy. Prevention of cerebral venous and thus intracranial hypertension can be achieved by neutral neck positioning, avoiding occlusive endotracheal tube ties and head-up positioning. Avoiding hypocapnia (Pa_{CO_2}<30 mmHg (3.99 kPa)), reducing cerebral metabolic rate with sedation, preventing hypoglycaemia and hyperthermia, and the use of anticonvulsants in those with documented seizures are simple measures to prevent secondary cerebral injury.

OTHER THERAPIES

There is no role for prophylactic corticosteroid therapy in the prevention of acute lung injury after submersion.[11] Prophylactic antibiotic therapy is unproven and the decision to commence therapy is made on the degree of water contamination, need for mechanical ventilation and severity of respiratory failure in each case.[15] Baseline microbiological studies should be sent prior to commencement of therapy.

PROGNOSIS

Mortality rate for those surviving more than 24 hours was 24% in a large series,[15] with three-quarters succumbing in the early stages after injury. Moderate to severe brain damage is reported in 33% of survivors.[7] The outcome in children is similar, with 30% having selective deficits and 3% with persistent vegetative state.[32] No difference in mortality between fresh- and salt-water submersion has been documented.[10] Lower core temperatures appear to be associated with a better prognosis, except if this occurs after rescue. However, hypothermia in warm-water immersion and severe hypothermia (<30°C) in cold-water immersion is indicative of prolonged immersion and poor outcome.[26] **Box 80.1** lists some factors associated with death or severe neurological impairment. None of these predictors is infallible and survival with normal cerebral function has been noted despite the presence of some or all of these factors.[33]

Box 80.1 Predictors of death or severe neurological impairment after submersion

At site of immersion
Immersion duration >5 minutes[34]
Delay in commencement of CPR >10 minutes[7]

In the emergency department
Glasgow Coma Score 3[35]
Fixed dilated pupils[36]

In the ICU
Glasgow Coma Scale <6 on arrival in ICU[37]
Arterial pH <7.0 on arrival in ICU[36]
No spontaneous, purposeful movements and abnormal brainstem function 48 hours after immersion[35]
Abnormal CT scan within 36 hours of submersion

Burns

David P Mackie and Jacqueline EHM Vet

The last half of the twentieth century witnessed a sustained improvement in the survival of patients suffering thermal injury. Arguably, the single most important development has been the establishment of centralised burn care, which made possible advances in fluid resuscitation, life support techniques and the prevention of infection. With optimal care, children and young adults with burns of more than 80% of total body surface area (TBSA) now stand a reasonable chance of survival.[1]

Improvements in survival have gradually led to a shift of emphasis in burn care towards qualitative aspects, such as rehabilitation and quality of life. The complexity of care has led to the concept of the multidisciplinary burn team, in which all aspects of care are coordinated in an integrated approach to clinical management.[1]

PATHOPHYSIOLOGY

LOCAL EFFECTS

Thermal injury produces complex local and systemic responses. The local inflammatory response results in vasodilatation and an increase in vascular permeability. The changes are immediate and combine to produce extravasation of fluid and plasma protein at the site of injury. In extensive burns, oedema becomes generalised. The greatest rate of oedema formation occurs in the first few hours, but further extravasation occurs up to 24 hours post burn.[2] The total amount of oedema formed depends on the extent of injury and the volume and rate of fluid administration. Without fluid replacement, hypovolaemic shock occurs, limiting the extent of extravasation. On the other hand, excessive fluid administration will produce excessive oedema. By 24 hours post burn, oedema formation is largely complete and vascular integrity restored.

The process of deepening of the burn wound beyond the area of heat necrosis following injury is at least partly due to microvascular stasis. Events occurring within minutes and hours of injury include microthrombus formation, neutrophil adherence, fibrin deposition and endothelial swelling. Diverse agents, including antioxidants and anti-inflammatory drugs, have been shown to attenuate this process in experimental settings, but none is yet established in clinical practice. Empirically, it is assumed that maintenance of good tissue oxygenation, avoidance of over-resuscitation and prevention of wound dehydration all contribute to wound healing by preventing undue extension of necrosis in the wound bed. Inotropic drugs are largely ineffective and should be avoided.

CIRCULATORY EFFECTS

Circulatory effects of burn injury become significant in burns of over 15% TBSA. Changes are rapid and the magnitude is roughly proportional to the extent of burn injury. Cardiac output is reduced immediately following injury. Secretion of epinephrine (adrenaline), norepinephrine (noradrenaline), vasopressin and angiotensin cause an increase in systemic and pulmonary vascular resistance. Circulating levels of agents with myocardial depressant properties, such as interleukin-1 (IL-1) and tumour necrosis factor alpha (TNF-α), are increased following burn injury, but developing hypovolaemia and increased blood viscosity may be equally important.[3]

Cardiac output recovers gradually during the second post-burn day, reaching supranormal levels by day 3 as the hypermetabolic response to burn injury becomes manifest. Circulatory dynamics are complicated by resorption of oedema fluid and by continuing evaporative fluid loss from the wounds. Prolonged elevation of renin/angiotensin and antidiuretic hormone (ADH) has been well documented and circulating blood volume may remain subnormal into the second week post burn.[4]

METABOLIC EFFECTS

The hypermetabolic state, which ensues from around the third post-burn day until the wounds are substantially healed, is a manifestation of the systemic inflammatory response syndrome. The state is partly sustained by evaporative and radiant heat loss through the wounds, and energy expenditure can be reduced by increasing the ambient temperature[5] and by the use of occlusive dressings.[6] Other factors known to influence

the metabolic rate include pain, fear and anxiety. There is also a suggestion that bacterial colonisation may aggravate hypermetabolism.[7,8] Burn patients often develop moderate pyrexia and leucocytosis, even when all microbial cultures are negative.

PHARMACOLOGICAL EFFECTS

The pharmacokinetics and pharmacodynamics of many drugs are altered in burn patients. During the first 24 hours, when the cardiac output is depressed, absorption and distribution of administered drugs are delayed. Thereafter, increased cardiac output leads to accelerated drug absorption and distribution, while oedema fluid acts as an ill-defined third space. At the same time, renal blood flow is increased, particularly in younger patients. Drugs excreted via this route, such as the quinolone and aminoglycoside antibiotics, may therefore fail to reach effective levels at conventional dosages.[9] On the other hand, toxic levels may ensue if renal failure supervenes. If possible, therefore, antibiotic administration should be guided by measurement of plasma concentrations.

Serum albumin levels are low in burn patients, and drugs bound to this protein, including some benzodiazepines, will show increased bioavailability. On the other hand, α_1-glycoprotein levels, which bind fentanyl, are increased. Detoxification via redox pathways such as cytochrome P-450 is depressed, lengthening the half-life of drugs such as diazepam.[10] Accumulation of benzodiazepine derivatives may be increased.

The pharmacodynamics of muscle relaxants are significantly altered owing to an increase in peri-junctional acetylcholine receptors.[11] Patients become relatively insensitive to non-depolarising agents, whereas administration of succinylcholine may give rise to excessive release of potassium, and cardiac arrest.

The burn wound is a significant route of drug absorption as well as drug loss. For example, the topical sulfonamide agent, mafenide, may cause metabolic acidosis through inhibition of renal carbonic anhydrase; deafness has been reported following the topical use of gentamicin.

CLINICAL MANAGEMENT

FIRST AID

Immediate aid comprises stopping the burn process, followed by the removal of clothing and cooling the wound, preferably with tepid, running water, for 10–20 minutes. This provides pain relief and may prevent deepening of the wound.[12] Hypothermia should be avoided. Oxygen should be given, if available, and patients with burns to head and neck should be kept in a semi-upright position. Burn injury can be assessed properly only in hospital conditions, and priority should be given to early evacuation of the victim.

GENERAL MANAGEMENT: 0–24 HOURS

On admission, a careful history should be taken of the circumstances of the injury, and to elucidate past medical history. The patient should be undressed, weighed and carefully examined to exclude additional traumatic injury. The extent and depth of injury are assessed with the aid of printed Lund and Browder charts, or by using the 'rule of nines' (**Fig. 81.1**). The rule of nines is modified for children (**Fig. 81.2**). A nasogastric tube and urinary catheter should be inserted in patients requiring resuscitation therapy. Escharotomies may be required for circular burns of the neck, trunk and limbs.

FLUID THERAPY: 0–24 HOURS

Fluid therapy is required for injuries exceeding 15% of body surface area (10% in children and the elderly), preferably via two wide-bore peripheral i.v. cannulas (preferably not in a burned area). The aim is to maintain moderate hypovolaemia by providing sufficient salt and water to preserve normal organ function while minimising oedema formation. Excessive fluid administration increases the risk of circulatory overload in the days following the resuscitation period. Potentially fatal complications of excessive fluid administration include the abdominal compartment syndrome in adults[13] and cerebral oedema in children.[14] An increasing tendency in recent years to over-resuscitate burn patients has been signalled.[15,16] In contrast to other

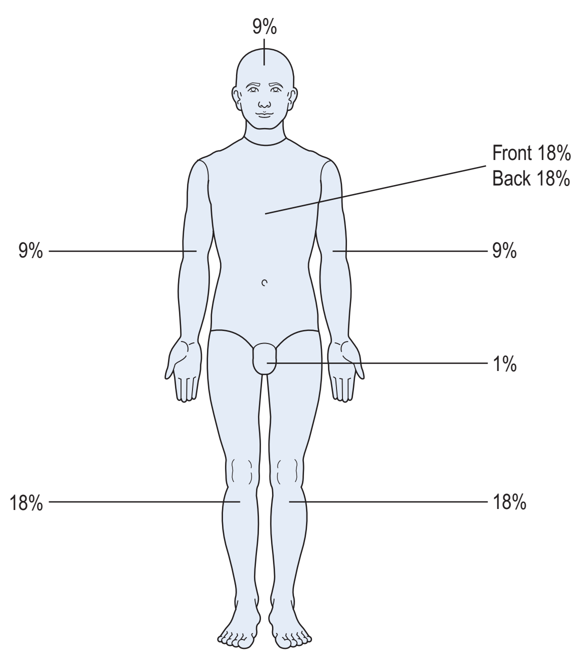

Figure 81.1 'Rule of nine' to estimate body surface area burns in adults.

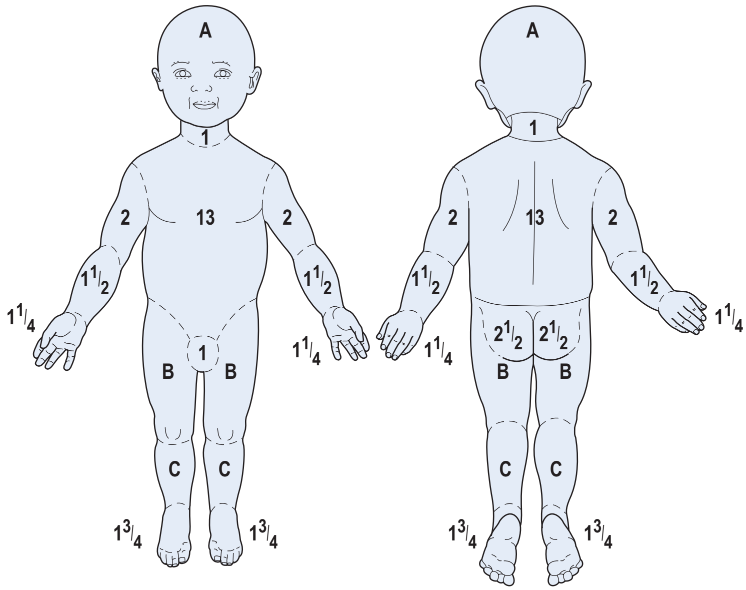
Figure 81.2 Surface area percentages by age.



Age	<1 year	1 year	5 years	10 years	15 years	Adult
Area A = $^1/_2$ of head (%)	9.5	8.5	6.5	5.5	4.5	3.5
Area B = $^1/_2$ of one thigh (%)	2.75	3.25	4.0	4.25	4.5	4.75
Area C = $^1/_2$ of one leg (%)	2.5	2.5	2.75	3.0	3.25	3.5

traumatic injuries, burn hypovolaemia is gradual, obligatory and predictable. Aggressive fluid administration will not restore the circulating volume[17] and, in the absence of frank shock, bolus fluids should not be given.

Various resuscitation formulae have been published in the past to guide initial fluid therapy. These formulae are entirely experience based and many are of historical interest only, but all comprise a fluid intake of 2–4 mL/kg body weight per % burn in 24 hours, and a sodium intake of approximately 0.5 mmol/kg per % burn.[18] These findings have led some to employ resuscitation regimens based on the administration of hypertonic sodium solutions, which require a smaller volume of fluid. However, the solute load may be excessive, requiring extra water administration in subsequent days, with an increased risk of fluid overload. The use of isotonic saline solutions is therefore preferred by those without experience of burns resuscitation.

The most widely used resuscitation formula for adults is based on the Parkland Formula, which has been adopted by major training programmes such as the Advanced Trauma Life Support and the Emergency Medicine for Severe Burns:

4 mL Ringer-Lactate solution × kg body weight × % TBSA burn in the first 24 hours; of which half should to be given in the first 8 hours post burn *and the other half in the next 16 hours.*

The formula thus incorporates a faster rate of administration if initial treatment has been delayed.

Children require extra fluid to compensate for basal needs. For children under 30 kg, the resuscitation formula of Carvajal[19] is useful:

$$\text{fluid requirement (mL): 0–24 hours post burn} \\ = (2000 \times \text{TBSA}) + (5000 \times \text{TBSAB}) \tag{81.1}$$

where TBSA is the total body surface area (m^2) and TBSAB is total body surface area burned (m^2). Again half of the calculated amount is given in the first 8 hours. For children under 1 year of age, one-quarter of the administered fluid should be glucose 5%.

These formulae are to be regarded as guidelines only. The actual amount of fluid given depends on the clinical condition and the actual amount of fluid administered can vary widely from that predicted. Adequacy of resuscitation is monitored by vital signs and a targeted urine output of 0.5–1 mL/kg per hour in adults and 1–2 mL/kg per hour in children. Other indicators include warm extremities and return of gut peristalsis. Fluid intake may be adjusted to maintain urine output at the desired range. Requirements are increased in the presence of mechanical ventilation, additional traumatic injury and dehydration (e.g. firefighters, intoxication).

Invasive monitoring is not essential in uncomplicated burns and the results may be misleading, as central pressures are invariably low. Hypoalbuminaemia develops rapidly and may be extreme. The extent to which burn patients will tolerate hypoalbuminaemia remains the subject of debate. In our unit at present, albumin is given to maintain serum albumin above 15 g/L, commencing 12 hours post burn when capillary integrity has been largely restored.

Thirst is common, but unrestricted oral fluids will increase oedema formation. Controlled quantities of nutritional liquids are recommended to protect gut integrity.[20] In patients with extensive injuries, tube feeding at a low rate can be commenced within a few hours of injury.

FLUID THERAPY AFTER 24 HOURS

During the second 24 hours, enteral nutritional intake is increased, while the total rate of fluid administration is gradually reduced. At the end of the second day, fluid intake should allow for generous urine production, while compensating for evaporative losses through the wounds.

The actual fluid loss through wounds varies widely, and depends on the type of burn and topical wound treatment. A useful formula to obtain a rough estimate for insensible fluid loss is:

$$(25 + \%\text{ body surface burn}) \times \text{m}^2\text{ body surface area} = \text{evaporative fluid loss (mL/h)} \tag{81.2}$$

Electrolyte disturbance is common following burn injury and requires treatment. Hypernatraemia is often a sign of dehydration, confirmed if serum urea is elevated. The condition is perilous, especially in the first week post burn, as oliguria and renal failure may develop unexpectedly. The amount of free water given should be increased gradually, particularly in the elderly, to avoid fluid overload. Patients who are in fluid balance may require sodium supplementation to compensate for solute loss in wound exudates.

HAEMOGLOBINUREA/MYOGLOBINUREA

Tissue injury from deep burns, particularly electrical injury, causes the release of myoglobin and haemoglobin from damaged cells. Diagnosis is made on observing discoloration of the urine, from faint pink in mild cases to almost black. Fluid administration should be increased; additional measures such as mannitol (12.5 g/L resuscitation fluid) to encourage diuresis and bicarbonate to alkalinise the urine may be considered, but the value of urine output as a guide to resuscitation is then lost.

PAIN THERAPY

During the first 24 hours, pain management is best achieved by incremental doses of i.v. morphine, or an equivalent opiate. Thereafter, the pain suffered by burn patients may be divided into background pain, which is continuous, and procedural pain caused by interventions.[21] The recurring ordeal of dressing changes, physiotherapy exercises and surgical procedures generates apprehension and anxiety, which compound distress.

Regular pain therapy is required to counter background pain, topped up by extra analgesics prior to procedures. In recent years, the advent of slow-release oral opiate medication has greatly improved the administration of analgesia. Procedural pain is best treated with continuous i.v. morphine or fentanyl, with titrated incremental boluses as required. Patient-controlled analgesia is effective, although modification of the control button may be necessary for those with bandaged hands. Ketamine in subanaesthetic doses is extremely useful for procedural pain in children. The influence of anxiety and depression on pain perception suggests additional avenues of therapy.[22] Non-pharmacological interventions, such as hypnosis and other distraction techniques, are an effective adjunct in susceptible patients.[23] Many burn patients may develop post-traumatic distress syndrome, and the emergence of symptoms may require additional support. Above all, an attitude of reassurance and understanding by all carers is indispensable.

NUTRITION

The hypermetabolic response is roughly proportional to the extent of injury. In young adults and children with extensive burns, energy expenditure may be doubled. In addition, protein and substantial amounts of trace elements, such as zinc, copper and selenium, are lost in wound exudate.[24]

There is no doubt that burn patients require additional calories and proteins, but traditional formulae for calculating requirements produce overestimates in the context of current burn care.[25] In the absence of direct metabolic measurements we currently use an empirical formula for estimating caloric intake:

$$\text{caloric requirement} = \text{REE} + (\text{REE} \times \%\text{ TBSA burn}/100) \tag{81.3}$$

where REE is the resting energy expenditure calculated from the Harris and Benedict equation.

Patients with extensive burns will require tube feeds, which are generally well tolerated. If gastric emptying is problematic, a post-pyloric tube is usually effective. PEG tubes are useful when facial burns are present. A high-protein proprietary feed is usually adequate, but should be supplemented by extra trace elements and vitamins. The possible benefit of glutamine supplements in burns has recently been reviewed.[26] Adequacy of feeding is best assessed by monitoring body weight.

Adjunctive therapy aimed at promoting anabolism includes the use of insulin to maintain normoglycaemia, the administration of oxandrolone (10 mg twice daily for adults),[27] and the use of propanolol to control tachycardia and extensive catabolism.[28]

WOUND HEALING

Treatment of extensive, full-thickness burn wounds by early excision and grafting has been firmly linked to survival.[29] Wound excision should be completed within the first week, before bacterial colonisation and neovascular infiltration of the wound bed develop. These operations are therefore urgent. Successfully grafted wounds will heal within 5 weeks, reducing the time available for bacterial infection to develop, and shortening the period of physiological disturbance. Wounds covered with widely meshed autografts lose large amounts of fluid unless protected by a semipermeable layer, such as allograft skin. Autograft donor sites are a further source of fluid loss.

For wounds treated conservatively, the main effort is devoted to the prevention of infection. Topical antimicrobial agents are commonly used, but may have potential side-effects (**Table 81.1**). These compounds change the appearance of the wound and should never be applied until expert wound inspection is complete. A number of biosynthetic materials are currently available, which are designed to improve cosmetic and functional outcome. Despite the use of antiseptic dressings or biosynthetic coverings, there is still a risk of microbial infection developing and unexplained signs of sepsis may necessitate urgent wound revision.

PREVENTION OF WOUND INFECTION

Bacterial infection is still the most common cause of death in burns. Depression of the immune system is well documented.[30] At the same time, the burn wound presents a favourable medium for bacterial growth.

BACTERIOLOGICAL SURVEILLANCE

Routine bacteriological surveillance of burn patients (at least twice weekly) is essential. The growth of pathogens from wound swabs may reflect growing resistance to topical wound therapy, indicating a need for change. When infection is suspected, the choice of an appropriate antibiotic will be governed by prior knowledge of the colonising micro-organisms and their antibiograms. In addition, the effectiveness of prophylactic measures can be assessed only by regular monitoring of the microflora present within the burns unit.

PATIENT ISOLATION

In an effort to reduce wound colonisation and contamination from cross-infection, barrier nursing of patients with extensive injuries is mandatory. The importance of isolation measures has been stressed,[31] but a significant proportion of patients still become colonised by micro-organisms from endogenous reservoirs, which cannot be controlled by barrier nursing alone.[32,33]

Table 81.1 Commonly used topical antimicrobial agents

AGENT	COMMENTS
Silver sulfadiazine (SSD)	The most widely used agent with broad-spectrum cover. Hypersensitivity (rarely) and transient leucopenia have been reported
Cerium nitrate 0.5%	Often added to SSD, and forms a stable eschar. It is reported to bind 'burn toxins'. Methaemoglobinaemia has been reported
Silver nitrate 0.5%	Applied as a soak, and is especially effective against *Pseudomonas*. However, it may increase sodium loss, and potentially can cause methaemoglobinaemia
Mafenide acetate 5–10%	Effective but short-lived antimicrobial, requiring repeated application. It has good penetration, and its side-effects (pain and metabolic acidosis) are less evident with 5% solution
Chlorhexidine	Aqueous solution (0.2%) or 1% gel provides broad-spectrum cover, but is rapidly inactivated, and may cause local pain, and rarely causes hypersensitivity
Nitrofurazone	In polyethylene glycol (PEG) solution it is effective against *S. aureus*, but resistance develops early. Side-effects include hypersensitivity (common), hyperosmolarity, and renal failure due to PEG absorption has been reported
Povidone iodine	In PEG solution provides broad-spectrum cover, but is rapidly inactivated. It prevents wound maceration. Side-effects include occasional hypersensitivity, renal dysfunction due to excessive PEG, metabolic acidosis and rarely dysfunction
Antibiotics	Have been used in solutions, creams, gels and sprays, but selection and development of resistant strains is inevitable, with a risk of systemic toxicity through absorption. Their usage is generally discouraged

Positive experiences have been reported with selective decontamination of the digestive tract,[8,34] but large-scale prospective trials have not been performed.

THE GASTROINTESTINAL TRACT

Loss of gut integrity following burn injury has been well demonstrated.[35] In addition to reactive damage following reperfusion of the ischaemic gut, mediators derived from the burn wound itself may also be involved.[36] Clinical strategies aimed at protecting the gastrointestinal tract include optimal fluid therapy during the first hours following injury to prevent mesenteric hypoperfusion, and the institution of early enteral nutrition, which can be safely commenced within a few hours of injury.[20] Diets enriched with glutamine may contribute to the maintenance of gut integrity.[26,37] Whatever the merits of each approach, all are secondary to the maintenance of effective hygienic policies in all aspects of patient care.

WOUND SEPSIS

Local effects include disruption of wound healing and deepening of the injury.

Systemic effects are often insidious. Prodromal signs are common and may include gastrointestinal stasis, increasing positive fluid balance, increasing insulin resistance and increasing pyrexia. As sepsis progresses, clinical deterioration becomes manifest: tachypnoea, circulatory instability, thrombocytopenia and oliguria may herald the onset of multiorgan failure. Leucocyte counts and C-reactive protein levels are affected by the systemic inflammatory response syndrome (SIRS) and are unreliable indicators in the absence of clinical signs and symptoms. Procalcitonin levels seem to be more reliable. Blood cultures are indicated if sepsis is suspected.

ANTIBIOTIC THERAPY

This is chosen on the basis of bacteriological surveillance data, and should be given early if possible. Evaporative fluid loss may increase if the wound surface degenerates. Supportive therapy for (multi-)organ failure should be implemented as indicated.

The causes of sepsis will persist until wound coverage is achieved, and operative wound treatment should not be postponed. Although mortality is appreciable, experience has repeatedly shown that the prognosis is by no means hopeless.

INHALATION INJURY

The term inhalation injury includes three distinct types of injury, which often, but not always, occur together. The presence of inhalation injury may increase resuscitation fluid requirements in patients with extensive cutaneous burns.

HEAT INJURY TO THE UPPER AIRWAY

Burns due to the inhalation of hot gases (steam excepted) rarely extend beyond the larynx. The development of mucosal and facial oedema can cause respiratory obstruction, particularly in children.

DIAGNOSIS

Facial burn, singed nasal hairs, visible burn to oropharynx and hoarseness are typical features.

TREATMENT

If the condition is suspected, early endotracheal intubation is safest, before the procedure is rendered hazardous by oedema formation. However, as mechanical ventilation may aggravate oedema formation, unnecessary intubation should be avoided.

EFFECTS OF SMOKE ON THE RESPIRATORY SYSTEM

Many of the chemicals that are contained in smoke are highly reactive and produce damage to the tracheobronchial tree. Detachment of epithelial cells and the development of tracheobronchial oedema cause airway narrowing and cast formation. Small-airway closure leads to hypoxaemia and respiratory failure. Later, bronchorrhoea and mucosal sloughing may cause atelectasis and provide a focus for infection. In the absence of a cutaneous injury the clinical course is usually benign. However, the presence of an extensive skin burn increases the likelihood of acute respiratory distress syndrome (ARDS); respiratory infection may follow.

DIAGNOSIS

There is a history of exposure in a confined space, cough, breathlessness, wheeze, stridor, hypoxaemia, and soot particles in the pharynx. Diagnosis is confirmed by bronchoscopy, which may reveal soot in the bronchial tree, mucosal injury and tracheobronchial oedema.

TREATMENT

Treatment is essentially symptomatic. Mild cases may be treated by high-flow oxygen administration by mask. In severe cases intubation and ventilatory support are necessary, with positive end-expiratory pressure (PEEP) to maintain small-airway patency. Regular bronchial toilet by bronchoscopy is recommended to clear debris and to prevent respiratory infection. Endotracheal tubes may become blocked with detritus. As small-airway obstruction is common, ventilation pressures may be adversely affected. Various strategies,

Table 81.2 Common inhaled toxic gases

GAS	SOURCE	EFFECT
Carbon monoxide	Organic matter	Tissue hypoxia, lipid peroxidation
Carbon dioxide	Organic matter	Narcosis, tachycardia, hypertension
Nitrogen dioxide	Wallpaper, wood	Bronchial irritation, dizziness, pulmonary oedema
Hydrogen chloride	Plastics	Severe mucosal irritation
Hydrogen cyanide	Wood, silk, nylons, polyurethane	Headache, coma, acidosis
Benzene	Petrol, plastics	Mucosal irritation, coma
Ammonia	Nylon	Mucosal damage, extensive lung injury
Aldehyde	Wood, cotton, paper	Mucosal irritation

such as high-frequency ventilation, have been advocated to minimise the risks of barotrauma.

Prolonged respiratory assistance may be necessary. The added respiratory requirements of the hypermetabolic state combined with inevitable loss of muscle mass frequently frustrate early weaning efforts.

INHALATION OF TOXIC GASES

Of the many toxic compounds[38] in smoke (**Table 81.2**), carbon monoxide (CO) deserves special mention. The affinity of CO for haemoglobin is 240 times that of oxygen. The loss of oxygen transport capacity is dependent on the concentration of inhaled CO and the duration of exposure. In addition, CO binds to cytochrome systems, inhibiting cellular oxidative processes. The half-life of COHb is 4 hours when breathing air, compared with 45 minutes when breathing 100% oxygen.

DIAGNOSIS

Carbon monoxide poisoning should be suspected in all cases of exposure to combustion products in a closed space. The classic cherry-red appearance of the CO victim is seldom evident; early signs may be mistaken for inebriation. Symptoms range from a throbbing headache in mild exposure (10–25% COHb) to weakness, dizziness, confusion and nausea (25–40% COHb), progressing to collapse, unconsciousness and convulsions (40–60% COHb). Death is increasingly likely at COHb concentrations of >60%. Patients exposed to high levels of CO may exhibit signs of cardiac instability. Signs of cerebral irritability may persist for days or weeks following apparent recovery.

TREATMENT

Administer the highest concentration of oxygen available, as soon as possible after exposure. Loss of consciousness is an indication for oxygen delivery via an endotracheal tube. The use of hyperbaric oxygen, if immediately available, seems logical, but additional benefit has not been proven.

HYDROGEN CYANIDE TOXICITY

Hydrogen cyanide (HCN) toxicity frequently occurs in conjunction with CO inhalation. Inhaled concentrations of 200 p.p.m. are rapidly fatal and HCN may account for many deaths at fire accident scenes.[39] Conventional treatment is as for CO intoxication. Removal by chelating agents, such as hydroxycobalamin, or by the administration of sodium thiosulphate, is also possible, but treatment would have to be immediate, based on a presumptive diagnosis and is therefore not generally recommended.

FUTURE PROSPECTS

The outlook for young patients with extensive burn injuries, treated under optimal conditions, is now such that little further progress may be expected in terms of survival alone. Mortality among the elderly does, however, remain high. The major thrust of research is currently directed at improving functional and cosmetic outcome following burns. Although the most visible efforts concern the development of techniques and materials to improve the quality of wound healing, advances in the field of intensive care are also relevant: strategies aimed at preventing ventilator-associated morbidity are equally applicable to burn patients, who often require prolonged ventilatory support; new insights into the inflammatory responses may improve the general condition of burn patients, increasing resistance to infection and improving tissue repair. There is growing interest in the psychological effects of thermal trauma, which includes new approaches to the management of pain and mental distress.

In the past, the establishment of burn centres has been largely opportunistic, often depending on the dedication of individual specialists. As the provision of medical services undergoes increasing scrutiny, the organisation of burn care in many countries may be subject to reorganisation. It is of the utmost importance that specialists involved in the field of burn care become actively engaged in this process, in order to guarantee continued quality of care for their population.

Thermal disorders

Stephen W Lam and Richard Strickland

NORMAL TEMPERATURE REGULATION

Humans are endotherms and maintain a remarkably constant core body temperature (T_c) across an ambient range that may exceed 100°C. In order to do so, humans produce heat via oxidisation of food substrates or use of stored energy. At equilibrium:

$$\text{energy input} = \text{external work} + \text{stored energy} + \text{heat} \quad (82.1)$$

Broadly speaking, heat production may be obligatory or facultative. Obligatory production is continuous and arises from processes essential for cell survival. The major components are the basal metabolic rate and the specific dynamic action of food. Facultative production is intermittent and arises from non-shivering thermogenesis in small amounts of brown adipose tissue, from shivering thermogenesis in skeletal muscle and as a by-product of physical activity. If the environmental temperature exceeds the mean skin temperature then heat will be gained from the environment; this generally occurs when the ambient temperature exceeds 35°C. Heat is lost by radiation, conduction, convection, and vaporisation of water from sweat and the respiratory tract. These mechanisms are limited by high ambient temperature or humidity. A very small amount of heat is lost in urine and stool.

The body may be visualised as having two thermal compartments: an outer shell comprising the skin and subcutaneous fat, and an inner core. The shell acts to protect the core and provide 'feed-forward' signals that allow the body to respond to potential thermal loads.[1] Current models of thermoregulation suggest T_c is maintained in an interthreshold zone or balance point by a series of relatively autonomous thermoeffector loops dependent on a common variable, T_c.[1,2] Although there is evidence for central reciprocal cross-inhibition of thermoeffector loops, the concept of a centrally regulated set point has now been replaced.

Temperature sensing occurs in skin, tissues of the deep core and centrally, providing afferent input to thermoeffector loops. In the dermis and epidermis, temperature-activated transient receptor potential (thermo-TRP) ion channels are found on free ending axons of dorsal root ganglia. Over 30 thermo-TRP channels exist and may be cold (predominant) or heat activated at differing thresholds.[3] Inputs from these channels travel the dorsal root ganglion to ascend via multiple pathways, including lamina one of the spinal cord and spinothalamic tract to the brainstem, where fibres for discriminative sensation and homeostatic control diverge.[1] Fibres for homeostatic control project to warm sensitive neurons in the preoptic anterior hypothalamus and cold-sensitive neurons in the posterior hypothalamus. Similar afferent inputs are derived from deep thoraco-abdominal musculature, large vessels and many organs. In addition, thermosensitive neurons in the preoptic anterior hypothalamus, circumventricular organs, the midbrain and spinal cord provide central sensory input.

When thermoafferent input reaches a threshold one or more thermoeffector loops are stimulated, with a resultant heat loss or heat gain response mediated via behavioural, autonomic or endocrine changes. Behavioural responses, which appear to be driven predominantly by peripheral input, are generally more energy-efficient, afford the greatest degree of thermoregulation and often pre-empt significant changes in T_c. If behavioural responses are inadequate or unavailable, as in many ICU patients, there is recruitment of autonomic regulation.

Autonomic responses are characterised by a threshold, gain and maximal response. An increase in T_c above 37°C results in a heat loss response comprising cutaneous vasodilatation and sweating mediated via predominantly cholinergic sympathetic nerves. When accompanied by an appropriate increase in cardiac output (≈3 L/min/°C), vasodilatation results in core to cutaneous heat transfer and increased heat loss. Skin blood flow may increase from a basal rate of 0.2 L/min up to 8 L/min at $T_c \approx 39.0$°C. Reflexes maintaining blood volume and pressure take precedence over thermoregulation. An inability to increase cardiac output or dehydration will reduce both the gain and maximal response of the vasodilator and sweating thermoeffector loops respectively.[2,4]

A decrease in T_c initiates heat-preserving responses. At a threshold of 36.8°C, sympathetic adrenergic vasoconstriction occurs, and then non-shivering thermogenesis commences in small amounts of brown adipose tissue. This is of more importance in infants and enables

heat production by uncoupling proton movement from ATP production across the mitochondrial inner membrane.[5] If T_c continues to fall toward 35.5°C then shivering thermogenesis begins, although the threshold and gain are reduced if the substrates for this process are inadequate – as may occur in hypoxaemia or hypoglycaemia.[2] Endocrine response includes increased secretion of cortisol and adrenaline.

The net effect of these mechanisms is maintenance of T_c around 36.9±0.4°C, with circadian variation of 0.5–1.0°C, peaking in the evening and being lowest around 6 a.m. T_c is less precisely regulated in young children who may exhibit greater diurnal variation. Whereas T_c is normally maintained in a narrow interthreshold zone, skin temperature may vary widely depending on ambient temperature and regional cutaneous blood flow. Temperature may vary amongst core organs by as much as 1.5°C during periods of rapid heat loss or gain, as in induction of therapeutic hypothermia or rewarming from cardiopulmonary bypass. The significance of this is uncertain, although it is worth noting that although the balance point at which T_c is normally maintained is close to the upper limit of survival, it is distant from the lower limit.

The ability to regulate temperature diminishes with age. In a thermoneutral environment T_c does not change in healthy older adults. When exposed to cold stress, peripheral vasoconstriction and thermogenesis are diminished both in threshold and in maximal response.[6,7] When exposed to heat stress, the elderly exhibit reduced sweat gland output and skin blood flow compared with younger controls.[6] When able, the elderly compensate for diminished autonomic thermoregulation with behavioural thermoregulation; however, this may be impaired when unwell, rendering the elderly prone to thermal insult.[6]

Patients in ICU are likely to have disturbances of both heat production and heat loss. Anaesthetic agents and opiates significantly reduce the threshold for heat loss response in a dose-dependent manner. Threshold for cutaneous vasoconstriction may fall to 34°C under general anaesthesia. Maximal response is also reduced by some agents although gain is unaltered.[8,9] In ICU sedation, cool ambient temperature, exposure, use of adrenergic, cholinergic and neuromuscular-blocking agents, ambient temperature fluid infusion, extracorporeal flow, impairment of neurological or cardiovascular function, or deficiencies of substrate for thermogenesis all alter the body's ability to maintain thermal homeostasis.

FEVER AND HYPERTHERMIA

Fever generally results from a cytokine-mediated change in threshold of thermoeffector loops resulting in regulated thermogenesis and transient elevation in T_c by 1–4°C. Hyperthermia results from failure of thermoeffector mechanisms to regulate temperature in the face of uncontrolled endogenous or exogenous heat gain. The primary event is not cytokine-mediated and T_c is usually well in excess of 40.0°C.

Various definitions of fever exist and are acceptable depending on the desired sensitivity of fever as an indicator of disease. Recognising differences in measurement technique, fever is often defined as a T_c>38.3°C.[10] Fever is common in the ICU and has many potential aetiologies (**Box 82.1**). Most are mediated by production of the pro-inflammatory cytokines IL-1, IL-6 and TNFα, which bind to receptors on circumventricular organs and up-regulate phospholipase A_2 resulting in production of prostaglandin E_2 via cyclo-oxygenase. This in turn stimulates warm-sensitive neurons in the preoptic anterior hypothalamus, shifting the threshold of cold-sensitive thermoeffectors by as much as 2°C, so inducing vasoconstriction and thermogenesis.[1,11] As pyrogen

levels fall, thermoeffector thresholds return to normal and T_c falls.

Mild to moderate fever is a phylogenetically preserved response and may provide survival benefit.[11] There is little evidence to suggest benefit from routine treatment of mild–moderate fever outside the setting of acute brain injury, cardiogenic shock or profound hypoxaemia.[12] As T_c progresses above 40.0°C, however, deleterious effects may occur and measures to control T_c should be considered whilst the underlying disorder is treated. In the case of fever, antipyretics may be adequate. Hyperthermias require active measures.

At a subcellular level hyperthermia has widespread effects that depend on both maximal T_c and duration of exposure. These include alteration of enzymatic function and protein folding that disrupts many cellular systems including ion channels, surface receptors, mitochondrial electron transport and cytoskeletal elements. Different individuals and cell lines exhibit different resistance to thermal injury. In general, short-term elevation in T_c to 40°C is tolerated without harm and may provide transient protection from further thermal injury via up-regulation of heat shock proteins.[13,14] Beyond this cellular and organ system dysfunction occur. These changes represent a spectrum of disease evolution with progressive damage as T_c or exposure duration increases. A T_c greater than 43°C is immediately life-threatening. Major organ system effects as core temperature rises are summarised in **Table 82.1**.

HYPERTHERMIAS

HEAT STROKE

Heat stroke represents the severest form of the spectrum of heat-related illness. It is characterised by T_c>40°C and neurological dysfunction ranging from restlessness to delirium, seizures and coma.[15] Heat stroke may be classified as either classic (passive) or exertional (active). Classic heat stroke occurs following exposure to high ambient temperatures in those at the extremes of age or with co-morbid disease or medications that affect thermoregulation (**Box 82.2**). Exertional heat stroke occurs in healthy individuals who undertake strenuous activity in environments with high ambient temperature and humidity, reducing the efficiency of radiative and evaporative heat loss. Although the incidence of certain organ dysfunction varies slightly between the two forms, management is the same and they will be discussed together.

The pathogenesis of organ dysfunction in heat stroke has been the subject of much research and our understanding remains incomplete. Elevations in T_c alter cellular and organ function as detailed above. The role of the cytokine response is unclear. In humans levels of TNFα and IL-6 have been correlated directly with severity of heat stroke.[15] In murine models pro- and anti-inflammatory cytokines were suppressed during onset of hyperthermia, rising 2–4 hours after maximal T_c was reached, and TNFα and IL-6 double-knockout mice exhibited increased heat stroke mortality.[16,17] It appears likely that components of the cytokine response serve a protective function.

Heat stroke is far more amenable to prevention rather than treatment. Most patients present with a delirium or coma, although focal neurology may occur. T_c is usually >40.5°C and patients are vasodilated with evolving distributive shock and multi-organ dysfunction. Sweating is not always present. Disorders that may present in a similar fashion require exclusion (**Box 82.3**). Management is essentially supportive; principles include the following:

- *Resuscitation:*
  - recognise the need for alveolar hyperventilation
  - restore circulating volume with cold 0.9% saline.
- *Cooling:*
  - accurately monitor core temperature (see section Core temperature measurement)
  - aggressively cool to return and maintain T_c<39°C (**Table 82.2**)
  - non-invasive measures that minimise cutaneous vasoconstriction and shivering are usually adequate.
- Org*an support:*
  - assess and support cardiorespiratory, renal, hepatic, haematological, endocrine and neurological function
  - hypotension usually responds to adequate cooling and volume replacement
  - seizures are probably best treated with benzodiazepines
  - prophylactic antibiotics are not recommended; however, endotoxaemia is a common complication and if clinically suspected appropriate cultures and Gram-negative cover are indicated
  - insulin receptor expression is down-regulated during hyperthermia, so there is a risk of hypoglycaemia after cooling with large initial doses of insulin.
- *Identify and manage precipitants (see Box 82.2):*
  - withhold agents impairing thermoregulation
  - treat underlying infection, dehydration or endocrine disorders.

The use of dantrolene has been reported in case series; however, it has been found to be ineffective.[18] Use of antipyretics is common although benefit has not been established and there is an association between the use of paracetamol and incidence of hepatic dysfunction.[15] The normal response to recovery from hyperthermia in mammals is biphasic, with initial hypothermia and then mild hyperthermia prior to restoration of thermal homeostasis. Traditional teaching has been to avoid hypothermia during recovery. In murine models prevention of hypothermia during recovery was associated with greater hypotension and mortality.[17] It is

Table 82.1 Organ system effects of change in T_c

20°C 28°C	30°C 32°C	34°C 35°C≈T_C	ORGAN SYSTEM	T_C≈38.3 → 40.0°C	42.0°C INCREASING TIME	44.0°C →
Cerebral metabolism falls by around 8%/°C Confusion progresses to coma, hyporeflexia, unreactive pupils Cerebral electrical activity is absent below 20°C			CNS	Increased CMRO and $CMR_{glucose}$ Reduced cerebral blood flow as Pa_{CO_2} falls	Agitation/Delirium Blood–brain barrier injury ↑ CSF protein/ lymphocytes	Coma, seizures Cerebral oedema Cortical infarction – especially cerebellum
Cardiac output halved at 28°C ↓ Contractility AF with slow ventricular rate at <30°C, VF at <28°C, Asystole at <20°C	Increasing PR, QRS and QT_c intervals (slowed K^+ flux) Osborne J wave below 33°C (height increasing with severity of hypothermia)	Initial increase in heart rate, then progressive fall (HR=45–55 at 33°C) ↑ Contractility±mild diastolic dysfunction V_{O_2} falls 8%/°C	CVS	Tachycardia, vasodilatation ↑ Stroke volume ↓ CVP/SVR Small decrease MAP Increase in V_{O_2}≈10%/°C	Progressive tachycardia Reduced stroke volume and MAP Reduced D_{O_2} if acidaemic	Hypotension/shock Myocardial infarction
Pulmonary oedema Apnoea	Respiratory depression ↓ Cough reflex ↑ Bronchial secretions ↓ Mucociliary clearance	↑ Respiratory rate and minute ventilation	Respiratory	Increased minute ventilation – mild respiratory alkalosis	Marked respiratory alkalosis±metabolic acidosis	Intravascular thrombosis Hypoxaemia ARDS
Fluid compartment shifting, haemoconcentration, blood viscosity increases ≈2%/°C Reduced platelet aggregation and adhesion at <35°C (decreased TxA_2 and glycoprotein Ib-IX) Reduced coagulation factors and platelet adhesion inhibitor (PAI) function at <33°C Non-linear reduction in both tPA and plasminogen activator inhibitor-1 activity; net result is unpredictable Hypercoagulability and DIC may also result			Haematological	Increased haematocrit if fluid intake inadequate	Direct activation of endothelium and platelets (increased vWF) Increased fibrinolysis Increased endothelial permeability	↑ Circulating tissue factor Microvascular thrombosis DIC Widespread haemorrhage Endothelial apoptosis

Hepatic and splenic sequestration causing thrombocytopenia and leucopenia Immune dysfunction (including white blood cells, reduced lymphocyte activation, natural killer cells, cytokines, complement)			Immunological	Leucocytosis Increased T- and B-cell activation, neutrophil/macrophage diapedesis and cytotoxicity ↓ Serum iron	Leucopenia Reduced cell-mediated cytotoxicity Lymphoid apoptosis and necrosis	
Acute tubular dysfunction	↓ ADH tubular ADH resistance	ANP release and diuresis Increased K^+, Mg^{2+}, Pa_4^{3-} excretion	Renal	↓ Renal blood flow	Tubular necrosis Glomerular microthrombus and haemorrhage	
Pancreatitis Lactic and ketoacidosis		↓ GI motility	Gastrointestinal	↓ Splanchnic blood flow	Enterocyte exfoliation – increased mucosal permeability	Bacterial translocation – endotoxaemia Intestinal infarction Pancreatic infarction
Reduced drug metabolism			Hepatic		Hepatocyte oedema and fatty infiltration	Haemorrhagic and coagulative necrosis, hepatic failure
↓ Catecholamine and cortisol secretion		↓ Insulin secretion and insulin resistance Glycogenolysis ↑ Catecholamine and cortisol secretion	Endocrine/metabolic	↑ Cortisol/glucagon secretion ↑ Metabolic rate	Insulin resistance Hyperglycaemia Hypokalaemia	Hypoglycaemia Hyperkalaemia Adrenal haemorrhage
Loss of shivering, rhabdomyolysis		Shivering	Musculoskeletal		Rhabdomyolysis	
Vasoconstriction			Skin	Vasodilatation (cutaneous blood flow ↑ up to 8 L/min) Sweat production	Vasodilatation Diminishing sweat production	Reduced cutaneous blood flow if cardiac output falls, anhydrosis

Box 82.2 Risk factors for heat stroke

Age
- Extremes of age

Environmental
- High ambient temperature and humidity
- Poor ventilation/lack of air conditioning

Behavioural
- Immobility
- Lack of acclimatisation
- Salt and water deprivation
- Obesity

Underlying conditions
- Cardiovascular disease
- Respiratory disease
- Infection/fever
- Diabetes
- Malnutrition
- Alcoholism
- Hyperthyroidism
- Impaired sweat production

Drugs
- Antihypertensives (angiotensin-converting enzyme inhibitors (ACEIs), beta blockers, diuretics)
- Butyrophenones and phenothiazines
- Anticholinergics
- Antiparkinsonians
- Antihistamines
- Tricyclics
- Sympathomimetics

Box 82.3 Differential diagnosis of hyperthermia

Environmental hyperthermias Heat stroke	CNS disease Status epilepticus Hypothalamic stroke Granulomatous disease
Drug-induced hyperthermia Malignant hyperpyrexia Neuroleptic malignant syndrome Serotonin syndrome Anticholinergic toxicity Sympathomimetic toxicity Salicylate toxicity MAOI toxicity Withdrawal (alcohol, benzodiazepines, baclofen)	Infectious Sepsis Encephalitis Meningitis Cerebral abscess Tetanus Malaria Typhoid
Endocrine disorders Thyrotoxicosis Phaeochromocytoma	Psychiatric disease Lethal catatonia

uncertain whether mild hypothermia should be allowed in humans during treatment for heat stroke.

Heat stroke mortality remains high with an in-hospital mortality of 65% being reported in a large, prospective observational study of classic heat stroke.[19] Those factors strongly associated with death included immobility, psychiatric or cardiovascular disease, T_c and number of organ failures at admission. Survivors often have significant long-term morbidity, predominantly secondary to neurological impairment.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a rare, autosomal dominant, pharmacogenetic myopathy with variable penetrance. It is characterised by a hypermetabolic state and skeletal muscle rigidity manifested when a susceptible individual is exposed to volatile anaesthetics or depolarising muscle relaxants. The disorder results from abnormal sarcoplasmic calcium flux and in 70% of cases is linked to a mutation in the ryanodine receptor RYR1. However, 30% of individuals with MH do not have RYR1 mutations, and other candidate proteins include calsequestrin-1 and the dihydropyridine receptor.[20] Upon triggering the abnormal RYR1 receptor is thought to release excessive calcium into the cytosol resulting in sustained excitation–contraction coupling. Sustained contraction and increased Ca^{2+}–ATPase activity result in increased aerobic glycolysis; however, muscle blood flow is reduced and eventually metabolism becomes anaerobic, with onset of metabolic acidosis.

Almost all cases are associated with use of a volatile anaesthetic±succinylcholine.[21] The earliest clinical sign is that of masseter spasm; however, this is neither specific nor sensitive. Hypercarbia disproportional to minute ventilation, sinus tachycardia and a rapidly rising temperature are the cardinal features, associated with generalised muscular rigidity in 40%.[21] These usually occur within 2 hours of exposure. In the ICU early diagnosis may be difficult as hypercarbia and tachycardia are common, although if out of keeping with the clinical situation or associated with other features such as muscular rigidity the diagnosis of MH should be considered. Fortunately the incidence of MH is extremely low if volatiles are avoided. Less common signs include tachypnoea, cyanosis, diaphoresis, cola-coloured urine, bleeding and ventricular dysrhythmias.

Triggering agents should be avoided in those with a history or family history of MH. If MH is suspected immediate management includes the following:

- Cease triggering agents. If using an anaesthetic circuit, flush the circuit. Increase minute ventilation.
- Give intravenous dantrolene 2.5 mg/kg rapidly. Repeat every 5–10 minutes until hypercarbia and temperature respond. Maximal initial dose 10 mg/kg (median required 6 mg/kg).[21]
- Treat hyperkalaemia/metabolic acidosis with bicarbonate.
- Cool the patient to T_c 36–38°C.

Table 82.2 Methods of temperature manipulation

CLASSIFICATION		METHOD	RATE OF CHANGE (°C/H)
Passive	Warming	Warm (>24°C) environment Insulating blanket	0.5–1
	Cooling	Cool environment Exposure (removal blankets/clothes)	
Active external	Warming	Warm forced-air blankets	1
		Water circulating heating control blanket	1
		Radiant heaters	1–2
		Temperature control pads (e.g. Arctic Sun, Medivance Inc., Louisville, CO)	1.5–3
	Cooling	Wet towels/ice packs	1
		Water circulating cooling control blanket	1
		Evaporative cooling (fan+tepid mist)	1–2
		Temperature control pads	1.5–3
Active internal	Warming	Humidified warm inspired gases	0.5–1
		Intravascular temperature control catheter (e.g. Alsius Coolgard, Irvine, CA; Celsius Control System, Innercool Therapies Inc., San Diego, CA)	2–4
		Body cavity lavage isotonic saline (gastric, right pleural 200 mL, peritoneal 10 mL/kg, bladder)	2–3
		Extracorporeal:	
		renal replacement circuit	5
		cardiopulmonary bypass	10
	Cooling	Cool intravenous fluids (4°C: 30–40 mL/kg)	2–3
		Intravascular temperature control catheter	2–4
		Body cavity lavage isotonic saline (gastric, right pleural 200 mL, peritoneal 10 mL/kg, bladder)	3
		Extracorporeal:	
		renal replacement circuit	5
		cardiopulmonary bypass	10

- Identify and treat complications:
  - cardiac arrhythmias:
    - usually respond to correction of hyperkalaemia and acidosis
    - avoid calcium antagonists, which may cause severe hyperkalaemia and cardiac arrest with high-dose dantrolene
  - rhabdomyolysis
  - disseminated intravascular coagulation (DIC).

All cases should be appropriately monitored until resolution. Dantrolene should be continued at 1 mg/kg 4–6-hourly for 24–48 hours. Failure to respond should prompt a search for an alternative diagnosis. Suspected cases should be referred to a MH screening centre. Testing usually includes a caffeine/halothane contracture test and genetic screening of relatives of confirmed cases for RYR1 mutations. Outcome of MH is good with mortality less than 10%. Additional resources are available from the Malignant Hyperthermia Association of the United States (http://www.mhaus.org/).

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome (NMS) is an idiosyncratic reaction characterised by hyperthermia, muscle rigidity, mental state change and autonomic dysfunction. It typically occurs within a month of introduction, or dose increment of an antipsychotic agent (including atypical antipsychotics). Other drugs that antagonise central dopamine transmission or rapid cessation of central dopamine agonist may also precipitate NMS.[22]

NMS is thought to occur as a result of central dopamine antagonism, predominantly at the D2 receptor. In the hypothalamus this results in hyperthermia, whilst mesocortical and nigrostriatal blockade result in mental state change and extrapyramidal symptoms respectively. It is postulated that a loss of central integration gives rise to autonomic instability.[22,23]

The clinical presentation is one of hyperthermia (usually <42°C), ‘lead-pipe’ rigidity, tachycardia, labile hypertension and delirium or coma. This may be accompanied by hypoventilation, diaphoresis, tremor, incontinence or mutism. Onset is usually over hours to

days and the diagnosis requires exclusion of other conditions that may mimic NMS (see Box 82.3). A peripheral leucocytosis is common, and creatine kinase is usually above 1000 IU/L; however, it may be much higher. Acute kidney injury and DIC complicate severe cases. Neuroimaging studies and CSF analysis are normal in 95% and EEG shows generalised slowing.[23]

Differentiation from other hyperthermias relies predominantly on drug and environmental history, the presence of hypertonia rather than hypotonia (heat stroke) and absence of serotonergic features. If there is clinical suspicion of infection then appropriate cultures including CSF should be performed after neuroimaging. If seizures are suspected an EEG is required.

Usually only severe NMS requires ICU support. Therapy includes:

- resuscitation – sedation±neuromuscular blockade may reduce severity of hyperthermia, rhabdomyolysis and other complications
- cessation of any potentially causative agent or re-introduction of acutely withdrawn dopamine agonist
- cooling to maintain T_c<39°C
- supportive care and management of complications:
  - respiratory failure (hypoventilation or aspiration)
  - rhabdomyolysis
  - AKI
  - DIC
  - arrhythmias
- potential adjunctive therapies including:
  - benzodiazepines or central alpha agonist for agitation
  - benzodiazepines for seizures or catatonia
  - bromocriptine 2.5–5 mg entrally 8-hourly
    - case series suggest reduced extrapyramidal symptoms and mortality
    - may worsen hypotension or psychosis
  - ECT – case series suggest ECT is safe and effective if NMS is prolonged or psychotic symptoms persist, although most patients were not in ICU.[24]

Dantrolene has been used in severe cases; however, there is no RYR1 abnormality in NMS and recent meta-analysis of published cases suggest no benefit.[23] Drug withdrawal and supportive measures are usually adequate and mortality is <10%. Psychiatric advice should be sought prior to re-introduction of antipsychotics.

SEROTONIN SYNDROME

A wide range of drugs are associated with the syndrome of serotoninergic toxicity. These include selective serotonin reuptake inhibitors (SSRIs), serotonin and norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs) (including linezolid and methylene blue), lithium, amphetamines, pethidine, fentanyl, tramadol, triptans and St John's wort. Severe serotonin toxicity occurs only after concurrent use of two or more serotoninergic agents, usually a SSRI and MAOI, and is thought to be mediated predominantly via the $5HT_{2A}$ receptor.[25]

Severe serotonin toxicity presents with altered mental state (agitation, delirium, coma), autonomic stimulation (tachycardia, hyperthermia, diaphoresis, tremor) and neuromuscular excitation (clonus, hyperreflexia, rigidity). Features with greater specificity for serotonin toxicity include hyperreflexia, lower limb or ocular clonus and myoclonus. Rigidity tends to be predominantly lower limb.[25]

Management of severe toxicity involves resuscitation, withdrawal of offending agents, cooling and supportive care. Complications are similar to those observed in the other hyperthermias. Adjunctive therapies are of less importance. These include the $5HT_{2A}$ agonist cyproheptadine, 4–8 mg enterally 6-hourly or chlorpromazine if enteral administration is not possible.

SYMPATHOMIMETIC TOXICITY

Hyperthermia may be precipitated by all centrally acting sympathomimetics by increasing release, inhibiting metabolism or preventing re-uptake of norepinephrine (noradrenaline), serotonin and dopamine, usually in a dose-dependent fashion. This results in increased muscle thermogenesis and impairs heat loss. In severe cases the clinical picture is that of a rapidly progressive hyperthermia with marked delirium or coma, rhabdomyolysis, DIC and multi-organ dysfunction. As with other severe hyperthermias, early and aggressive supportive care is indicated. Intubation, neuromuscular blockade and aggressive cooling are often required. Plasma potassium may rise very rapidly and require dialysis. There are no specific therapies and although dantrolene has been advocated there is insufficient evidence to support routine use.

ANTIMUSCARINIC TOXICITY

A wide variety of antimuscarinic agents exist. Peripheral toxicity causes tachycardia, cutaneous vasodilatation, mydriasis, urinary retention and impaired sweating. Central toxicity gives rise to tremor, delirium and occasionally seizures. Severe hyperthermia with rhabdomyolysis and DIC may occur; however, this is unusual and most antimuscarinic toxidromes are adequately managed with drug withdrawal, titrated benzodiazepine and passive cooling.

HYPOTHERMIA

DEFINITION AND CLASSIFICATION

Hypothermia is defined as core temperature less than 35°C, and it may develop due to abnormal

Box 82.4 Important causes and contributors of hypothermia

Increased heat loss
- Surface conduction, convection, radiation, or evaporation
- Vasodilatation, dermatological disruption
- Extremes of age

Reduced heat production
- Endocrine (e.g. diabetic ketoacidosis, hypopituitarism, hypoadrenalism, hypothyroidism)
- Reduced energy reserve or substrate (e.g. hypoglycaemia, malnutrition, hypoxaemia)
- Immobility and reduced neuromuscular activity
- Extremes of age

Impaired or abnormal central thermoregulation
- Central nervous system disorders
- Pharmacological and toxicological (e.g. alcohol, CNS depressants, psychotropics)
- Uraemia
- Sepsis
- Malignancy

thermoregulation or heat loss overwhelming thermoregulatory capacity. Important causes and contributing factors are summarised in **Box 82.4**.

Severity is somewhat arbitrarily classified as:

- mild (32–35°C)
- moderate (28–32 °C)
- severe (T_c<28 °C).

Hypothermia may be unintentional (often referred to as 'accidental'), or intentional (therapeutic hypothermia, TH). This can be further divided into:

- primary (intact thermoregulation)
- secondary (abnormal thermoregulation)
- tertiary hypothermia (induced for therapeutic purpose, as in TH).

PHYSIOLOGICAL EFFECTS OF HYPOTHERMIA

Hypothermia alters a wide range of molecular and cellular functions, some of which may be exploited for therapeutic purpose. However, prolonged or severe hypothermia causes progressive deterioration in organ function.

Manifestations of the normal thermoregulatory response predominate in patients with cold exposure or very mild primary or tertiary hypothermia (generally with T_c above 34°C). Patients with abnormal thermoregulatory capacity (especially those with dysautonomia) may lack some of these features and are more prone to developing secondary hypothermia. There is an increase in catecholamine and cortisol secretion, and sympathetic activation is evident with:

- increase in respiratory rate
- increase in heart rate and contractility
- mild diastolic cardiac dysfunction
- vasoconstriction with reduced tissue perfusion
- increase in muscle tone and shivering. This can increase heat production and oxygen consumption several-fold, but largely settles at temperatures below 34°C. Application of surface warming and the use of alfentanil, fentanyl, pethidine, propofol, dexmedetomidine, clonidine, or magnesium are often effective in reducing shivering.

The Swiss staging system describes five clinical stages of severity in primary hypothermia:[26]

- *stage I:* clearly conscious and shivering
- *stage II:* impaired consciousness without shivering
- *stage III:* unconscious
- *stage IV:* no breathing, no signs of life
- *stage V:* death due to irreversible hypothermia.

Table 82.1 provides a summary of the physiological effects of hypothermia.

MANAGEMENT OF PATIENTS WITH ABNORMAL CORE TEMPERATURE

This section provides a summary of some important clinical considerations in the management of patients with abnormal core temperature.

CORE TEMPERATURE MEASUREMENT

The temperature of blood perfusing the hypothalamus is considered the reference point for T_c. The pulmonary artery catheter is the most accurate means for temperature measurement.

Compared with pulmonary artery catheters, the most accurate means of temperature measurement are oesophageal probe in the lower quarter of the oesophagus (0.11±0.3°C) and urinary bladder catheter (−0.2±0.2°C). Less accurate are rectal, inguinal and axillary measurements.[27–29]

Urinary bladder temperature measurement is less reliable in oliguria. The accuracy of tympanic measurements is somewhat variable and may be inaccurate in significant hypothermia, while oesophageal temperature measurement may be influenced by gas temperature in the trachea.[29,30]

There may also be differences of around 1.5°C between regions of the body and brain, particularly during rapid temperature change, and cerebral thermopooling (regions of increased brain temperature) can occur.[31,32]

PHARMACOLOGICAL EFFECTS OF ALTERED BODY TEMPERATURE

Much work in this area has been performed on animal models and understanding of drug pharmacology in

humans during hypothermia or hyperthermia is limited. Although each drug requires characterisation across temperatures, some principles provide guidance.

Febrile patients with SIRS may have high cardiac output with resultant increase in renal and hepatic blood flow. Augmented renal clearance of a number of antimicrobials has been well described in subgroups of ICU patients.[33] Although hepatic blood flow may increase, the acute phase response suppresses expression of many cytokines and the net effect of fever on hepatic clearance in humans is uncertain. In severe hyperthermia organ dysfunction is likely to result in markedly altered pharmacokinetics.

In hypothermia, absorption of orally administered drugs is significantly slowed. Bioavailability, depending upon hepatic extraction, varies between drugs. Effect on volume of distribution (Vd) is variable as tissue blood flow, protein binding and ionisation change. For example, the Vd of midazolam increases 83% at 33°C, whilst the Vd of pancuronium decreases.[34] Altered ionisation is of significance in drugs with a pKa between 7–8 and narrow therapeutic window (e.g. lidocaine). In this setting pH-stat ventilation may be wise.[34] Hypothermia reduces hepatic blood flow and slows enzyme kinetics resulting in reduced hepatic and extrahepatic clearance. Renal flow, glomerular filtration rate (GFR) and tubular secretion are also reduced.[35] In moderate hypothermia clearance of propofol, morphine and vecuronium are reduced by 10–25%.[34] Pro-drugs therefore have a slower onset, whereas active drugs and those with active metabolites have prolonged duration of action and increased risk of toxicity.

Pharmacodynamic changes with hypothermia are variable and poorly characterised. Rewarming brings about further kinetic and dynamic alterations. In patients with significant alterations in T_c it seems wise to dose parenterally, avoid pro-drugs and agents with multiple active metabolites, and when possible titrate to a clinical end-point or undertake temperature-corrected therapeutic drug monitoring.

ACID–BASE AND BLOOD GAS INTERPRETATION

Blood gas analysers heat or cool samples to 37°C at which they are calibrated to perform measurements. Deviation in body temperature from 37°C therefore results in a difference between the patient's true values and those derived from the blood gas analyser, which may be clinically significant.

The solubility of a gas is inversely related to the temperature of the solution. Therefore, a hypothermic patient will actually have lower Pa_{O_2} and Pa_{CO_2} than values derived from blood gas analysis performed at 37°C, whereas the opposite is true in fever and hyperthermia (Henry's law). The relationship between temperature and gas solubility is non-linear and correction factors are required to estimate true blood gas values in the patient.[36]

Because cerebrovascular reactivity to Pa_{CO_2} is preserved, calculation of the patient's true Pa_{CO_2} may be relevant in patients with raised intracranial pressure. Maternal acid–base status may also be particularly relevant to the fetus during pregnancy.[37,38]

VENTILATION STRATEGIES

Data on ventilatory strategies are mostly derived from patients undergoing hypothermic cardiopulmonary bypass and therapeutic hypothermia following central nervous system injury. It is uncertain whether mechanical ventilation should be adjusted to achieve Pa_{CO_2} and pH targets according to the arterial blood gas values measured at 37°C (alpha-stat method), or corrected to the patient's body temperature (pH-stat method).[39–41]

Regardless of ventilation strategy, it should always be noted that measured Pa_{O_2} is not the true patient value if T_c is significantly greater or less than 37°C.

ALPHA-STAT STRATEGY

This strategy is based on the theory that maintaining the pH of neutrality (pN) is important for cellular enzyme function and metabolism. The imidazole group of histadine is an important component of protein acid–base buffering, and has a pN that changes with temperature. Imidazole ionisation fraction (denoted as alpha) remains constant as body temperature changes (if CO_2 content also remains constant) thereby maintaining constant net charge of proteins and maximal ionisation of intracellular metabolic intermediates. When applying alpha-stat theory, measures are taken to adjust Pa_{CO_2} to meet its target value at 37°C, without being corrected for actual patient temperature.

PH-STAT STRATEGY

This strategy is based on the theory that pH should be kept at its target value throughout the range of patient temperatures, and that cerebral blood flow autoregulation continues to react to Pa_{CO_2}. There is no reference range for temperatures other than 37°C, and the pH-stat approach assumes that values appropriate for 37°C remain so for all temperatures. This may be particularly relevant in patients with narrower Pa_{CO_2} and/or pH targets, such as those with raised intracranial pressure and in pregnancy.

Use of pH-stat in hypothermic patients requires an increase in CO_2 content, and therefore results in cerebral vasodilatation above the brain's metabolic demand, which may worsen pre-existing intracranial hypertension. It does, however, counteract the leftward shift in the oxyhaemoglobin dissociation curve caused by hypothermia.

TRANSCUTANEOUS PULSE OXIMETRY RESPONSE TIMES IN HYPOTHERMIA

In hypothermic patients the detection of changes in haemoglobin oxygen saturation by transcutaneous

pulse oximetry may be significantly slower using finger probes compared with forehead sensors.[42]

HAEMOSTATIC ASSESSMENT

In the same manner as blood gas analysis, common tests of haemostasis such as the thromboelastograph (TE), activated partial-thromboplastin time (aPTT), and prothrombin and thrombin times are measured with blood samples at 37°C. Hypothermic effects on platelet and coagulation enzyme function are reversible with rewarming, and hence laboratory values may be misleading when considering the patient's haemostatic capacity.[30,43] Measurements can be performed at other temperatures with prior calibration of equipment.

MANAGEMENT OF CARDIAC ARREST

No recommendations for modification of standard cardiopulmonary resuscitation have been made for fever or hyperthemia.

Severe hypothermia can produce a clinical state that mimics prolonged circulatory arrest and poor prognosis with apnoea, asystole, unreactive pupils and areflexia. However, good outcomes have been achieved with prolonged resuscitation in such patients and efforts should be continued in conjunction with aggressive rewarming until return of spontaneous circulation or T_c of 35°C is achieved.[44] Rewarming is important in restoring perfusing cardiac rhythm in patients with VF or VT and may also resolve atrial arrhythmias, atrioventricular block and bradycardia.

The optimal dose and timing of defibrillation and drugs in hypothermic cardiac arrest patients have not been established.[45] Recommendations for reducing or withholding drugs and defibrillation in hypothermic cardiac arrest patients are based on mostly theoretical concerns over cardiac unresponsiveness to drugs and defibrillation, and reduced drug metabolism that might result in drug toxicity with repeated dosing.[44]

The suggested modification for cardiopulmonary resuscitation of hypothermic patients involves:[46]

- withholding drugs until temperature is >30°C, then doubling usual drug intervals until temperature is >35°C
- delivery of up to three shocks using maximum energy for VT or VF, and thereafter withholding further shocks until temperature is >30°C. Rhythms other than VF may revert spontaneously with rewarming.

The optimal timing and dose of cardiac arrest drugs is not known for normothermic or hypothermic patients. Animal studies have found vasoactive drugs and defibrillation to be effective in the setting of hypothermia, and success in humans has been reported.[44,47] Currently, there is inadequate evidence to make strong recommendations on how to modify standard cardiopulmonary resuscitation algorithms in the setting of hypothermia.[44]

TEMPERATURE MANAGEMENT AND CONTROL

CONTROLLING FEVER AND HYPERTHERMIA

In the patient with severe hyperthermia, early aggressive pharmacological and physical measures are indicated to reduce or avoid the adverse consequences of elevated T_c. Sedation, intubation and neuromuscular blockade may be required in severe cases. Physical methods that are rapidly available and achieve high cooling rate should be employed (see Table 82.2).

In the case of fever, and especially sepsis, the concept of manipulating T_c is somewhat more controversial. Although controlling fever may reduce metabolic workload (unless uncontrolled shivering occurs) and appears to reduce vasopressor requirement in septic shock, its net effect on immune function, development of acute lung injury and survival are unknown.[48–51] Similarly, whilst fever and hyperthermia cause secondary neurological injury, benefit from controlled normothermia is yet to be conclusively demonstrated.[52]

Where temperature is pyrogen-mediated the use of an antipyretic such as paracetamol seems logical, although this has been questioned by some animal studies.[53] Paracetamol acts predominantly by central inhibition of cyclo-oxygenase and results in temperature reduction of 0.3–0.4°C, without inducing a counter-regulatory response.[54] Other agents that suppress thresholds for thermogenesis and may be appropriate in the non-ventilated patient include magnesium, opiates, benzodiazepines, clonidine and tramadol.[39]

Control of fever or maintenance of normothermia in the non-sedated, non-intubated patient can be challenging if thermoregulation is intact, with the balance point for T_c often being elevated by endogenous pyrogens or direct hypothalamic insult. The application of physical modes of cooling without pharmacological measures to alter thermoeffector response results in shivering and increased cardiorespiratory workload. In such cases, the risks associated with need for sedation and even intubation and paralysis in order to achieve additional cooling must be weighed against potential benefit of temperature control.

CORRECTING HYPOTHERMIA

The various methods of increasing core temperature are summarised in Table 82.2.

In general, it is considered that:

- for patients with intact autoregulatory thermogenesis and temperature >34°C, passive rewarming alone may be adequate
- patients with spontaneous circulation and temperature <34°C often require addition of active external warming
- patients with temperature <30°C usually require active internal warming; extracorporeal techniques

are the most effective and are generally required in the setting of cardiac arrest.

Warming of intravenous fluid (generally to around 40°C) prior to administration is important in limiting further hypothermia, but is an inefficient means of rewarming. Gastric and bladder irrigation also have limited effectiveness.

During rewarming, care should be taken to avoid precipitation of cardiac arrhythmias by sudden movement and invasive intervention; however, this concern should not influence the performance of life-supportive manoeuvres such as intubation and central venous catheterisation, and it is very rare at temperatures above 30°C.[39,44,46] Hyperkalaemia may develop due to extracellular shifting, and the return of insulin sensitivity may result in potentially detrimental hypoglycaemia and high blood glucose variation.[55,56] Rapid rewarming causes cerebral vasodilatation and impairs cerebral blood flow autoregulation, and hence any intracranial hypertension would be expected to worsen. Vasodilatation often results in the need for intravenous fluid administration; however, the potassium (and perhaps lactate) content in lactated Ringer's solution may be problematic in hypothermic patients being rewarmed.

In patients who have become hypothermic due to surface heat loss, the temperature of the peripheral compartment may be lower than the core compartment. Active surface rewarming in these patients may cause peripheral vasodilatation with blood circulating to the cooler peripheral compartment returning to the core compartment at a lower temperature. This 'core temperature afterdrop' may be mitigated by using active internal rewarming prior to or concurrent with surface rewarming.

RATE OF REWARMING

Concerns in addition to the hazards of sudden physiological change during rewarming have been raised more recently, mostly in the literature on patients undergoing cardiopulmonary bypass or TH. These include:

- that rapid rewarming exacerbates neurological injury and compromises cerebral blood flow autoregulation[57,58]
- a possible association with seizures on rewarming[59,60]
- discrepancy between cerebral and core temperatures during rewarming[30–32,61,62]
- findings of better neurocognitive and renal function following slow rather than fast rewarming from cardiopulmonary bypass.[63,64]

THERAPEUTIC HYPOTHERMIA AND TARGETED TEMPERATURE MANAGEMENT

Hypothermia is potentially beneficial in a variety of circumstances and is the subject of intense laboratory and clinical research interest. The combination of biological plausibility of benefit, positive animal data and some positive human trial data has resulted in its introduction as a therapeutic modality in some circumstances.

POTENTIAL MECHANISMS

Most mechanisms of potential benefit with TH relate to the modification of temperature-sensitive consequences of cellular injury, with particular focus at present on tissues of the central nervous system in the setting of ischaemia or reperfusion. Traumatic or ischaemia/reperfusion injury results in a cascade of destructive processes ranging from subcellular to systemic levels that can continue for several days and perhaps even weeks.[52] A wide range of these processes are temperature-sensitive; however, their duration of such varies following an insult. The clinical implications of this variability such as on optimal timing and duration of TH has not been fully elucidated.[62] **Box 82.5** lists some of the effects of hypothermia with potential benefit for the central nervous system.

Potential benefit may also be derived from its physiological effects such as those on vascular tone and the immune function (in patients with sepsis and septic shock), and reduction of intracranial pressure.

INDICATIONS FOR THERAPEUTIC HYPOTHERMIA

Current consensus amongst resuscitation councils and critical care societies is that:[45,58,65–68]

- therapeutic hypothermia is strongly recommended on the basis of a moderate to strong level of evidence

Box 82.5 Mechanisms of neuronal benefit with hypothermia[52,62]

Early mechanisms

- Reduction in cerebral metabolism (≈8% reduction per 1°C fall) and thermopooling
- Reduction in mitochondrial dysfunction
- Decreased production of nitric oxide and free radicals
- Decrease in excitatory neurotransmitters and calcium influx

Late mechanisms

- Suppression of ischaemia-induced inflammation
- Mitigation of reperfusion-related DNA injury, lipid peroxidation and leukotriene production
- Reduced cell membrane leakage and cytotoxic oedema, blood–brain barrier stabilising effect
- Suppression of seizures
- Reduction in apoptosis (inhibition of caspase activation)

Adapted from: Polderman KH. Mechanisms of action, physiological effects, and complications of hypothermia. Crit Care Med 2009;37(7):S186–202.

for use in adult survivors of out-of-hospital cardiac arrest of cardiac cause with initial rhythm ventricular fibrillation (VF) or ventricular tachycardia (VT), who do not demonstrate meaningful response to voice following return of spontaneous circulation, ROSC (target temperature 32–34°C, maintained for 12–24 hours, rewarmed at a maximum rate of 0.5°C/h)
- therapeutic hypothermia *may* be beneficial and *should* be considered on the basis of extrapolation and weaker levels of evidence for use in:
  - adult survivors of in-hospital cardiac arrest and cardiac arrest of non-shockable rhythm or non-cardiac cause
  - neonates born at ≥36 weeks' gestational age with evolving moderate to severe hypoxic ischaemic encephalopathy (target 33.5–34.5°C, commenced within 6 hours of birth, maintained for 72 hours, rewarmed over at least 4 hours).

Other conditions for which therapeutic hypothermia is being investigated include traumatic brain injury, spinal cord injury, neurosurgery, ischaemic and hemorrhagic cerebrovascular accident, myocardial infarction, cardiogenic shock and liver failure.[52,58]

METHOD

It is currently recommended that TH be provided using similar temperature profiles to those used in human trials, which demonstrated positive outcomes; however, the optimal timing and method of TH are still uncertain.

The risks of TH are most likely to be outweighed by potential benefit in high-level intensive care units with a practice guideline specific for the institution. In addition, it is recommended that a tightly controlled temperature profile over discrete stages of induction, maintenance, reversion and post TH be prescribed. This is referred to as targeted temperature management (TTM); the use of imprecise temperature targets and methods of temperature measurement and control is potentially hazardous.[58]

Induction of TH is generally carried out as quickly as possible, aiming to achieve target temperature within 8 hours of return of spontaneous circulation in the case of post-cardiac-arrest care. In addition to targeting destructive processes that are temperature-sensitive for only a few hours following insult, rapid induction also limits shivering, diuresis and electrolyte loss, fluid compartment shifting and haemodynamic fluctuation, all of which tend to settle once the temperature falls below 33.5°C.[39] Current recommended timeframes for achieving target temperature are derived only from some animal and trial data, and the true therapeutic window is presently unknown.[66,69]

Methods of rapidly inducing TH include (see Table 82.2):

- 4°C intravenous crystalloid fluid bolus of up to 30 mL/kg over 30 minutes
- surface ice packs or cold-air blankets
- temperature control devices with external pads (e.g. Arctic Sun) or intravascular catheters (e.g. Alsius Coolgard, Celsius Control System)
- intranasal evaporative coolant delivery (e.g. Rhinochill, BeneChill, San Diego, CA)
- cooling helmet.

Cold intravenous fluids have been used in pre-hospital initiation of TH and can rapidly lower temperature by around 1.5°C.[66] Numerous studies found no convincing increase in complications (including pulmonary oedema); however, cold fluids alone are not sufficient to maintain hypothermia.[68]

The optimal duration of TH is unknown and may vary between individual cases depending on circumstance and the nature of illness or injury.[62] Current recommendations of 12–24 hours in adults and 72 hours in neonates are based on the methods used in clinical trials with outcome benefit in favour of TH.

Rewarming is recommended to be tightly controlled at a rate of 0.25–0.5°C/h. Although the optimal rate of rewarming is not known, the prevention of rapid rewarming and rebound hyperthermia is thought to be important and often requires active temperature modulation through the use of a temperature control device.[62]

Hyperthermia is common following cardiac arrest and is thought to be an important mechanism of secondary neurological damage. It is recommended that normothermia be maintained beyond the period of TH; however, there is no evidence at present that this improves patient outcome.[66]

Temperature control devices use continuous temperature feedback from patient monitoring (such as oesophageal and bladder catheters) or intermittent intravascular temperature measurements (Celsius Control System) to adjust closed-loop fluid or catheter temperature. These devices do not involve administration of extra fluid, and use conductive cold or heat between device and skin (surface devices) or blood (intravascular devices). They can achieve cooling rates of up to 4.5°C/h and are the most precise methods of controlling temperature through all stages of TTM.[39,70–72]

CLINICAL CONSIDERATIONS DURING TH

All of the physiological effects of hypothermia as discussed earlier in this chapter and their implications on patient management should be borne in mind when applying TH. Of particular importance are:

- its effects on potassium and glucose levels
- interpretation of arterial blood gases and acid–base status
- potential masking of fever due to sepsis
- effects on pharmacokinetics and pharmacodynamics
- the use of anticoagulation and thrombolysis
- safety with percutaneous coronary intervention (PCI)

- potential for worsening of cardiac output and arrhythmias
- its implications in pregnant patients
- potential need to control shivering with sedation and paralysis
- neurological prognostication following anoxic brain injury.

ANTICOAGULATION AND THROMBOLYSIS DURING TTM

There is very little published data on the effect of TH on patients receiving anticoagulation and/or thrombolytic therapy. In the two major trials with outcomes in favour of TH following cardiac arrest, anticoagulation and thrombolytics were used as required; however, only one patient in one study and 27 patients in the other received both TH and thrombolysis.[69,73]

Hypothermia can reduce both tPA and plasminogen activator inhibitor-1 (PAI-1) activity; however, these effects appear non-linear and the net result is unpredictable. No clear change in incidence of intracranial haemorrhage was found in a preliminary study of TH commenced 30–180 minutes following thrombolysis in patients with ischaemic stroke.[74]

TTM AND PERCUTANEOUS CORONARY INTERVENTION (PCI)

Coronary arterial dilatation can occur in response to cold skin contact and mild hypothermia, however vasoconstriction can occur in diseased coronary arteries.[75] Results are somewhat mixed in the very limited data available on the impact of TH on outcomes in patients receiving PCI. The introduction of protocolised TH to patients undergoing PCI may be associated with a higher incidence of infection and need for blood transfusion compared with historical controls.[76,77] In patients treated with TH, those undergoing PCI may not have a higher rate of complication compared with patients not undergoing PCI.[78] It is currently considered safe to provide patients with both TH and PCI.[68]

TTM IN PATIENTS WITH CARDIOGENIC SHOCK

The use of hypothermia in cardiogenic shock may improve haemodynamic stability with an increase in both systemic vascular resistance and stroke volume; however, it may also increase oxygen consumption and demand if shivering is not controlled.[79,80]

There is limited published evidence on the use of TH in patients with cardiogenic shock,[81,82] and importantly there has not been a direct comparison of outcomes between patients with cardiogenic shock treated with TH and patients with cardiogenic shock not treated with TH.

Patients with significant shock (defined as systolic blood pressure less than 60 mmHg (7.98 kPa) despite epinephrine infusion, or mean arterial pressure less than 60 mmHg (7.98 kPa) for greater than 30 minutes) were excluded from the two major trials on cardiac arrest patients.[69,73]

There are some data to suggest that the incidence of ventricular arrhythmias, bleeding, and infection may not be higher when TH is used in patients with cardiogenic shock compared with patients without cardiogenic shock.[82]

THERAPEUTIC HYPOTHERMIA IN PREGNANCY

There are published cases of therapeutic hypothermia in pregnancy; however, there is a lack of trial data and pregnant patients were excluded in the clinical trials that demonstrated benefit with TH. Good maternal outcome with subsequent delivery of an apparently normal neonate has been reported following the use of TH at 13 weeks' gestation,[83] although fetal demise has also been reported during, but not necessarily as a result of, TH.[84]

Given the weight of evidence supporting improved outcomes for a subset of adult survivors of cardiac arrest, it is reasonable to consider the use of TTM in a pregnant woman.

The following should be noted when considering or applying TTM during pregnancy:

- evidence is lacking on the safety of TH for the fetus
- both hypothermia and rewarming can increase uterine tone and contractions, which reduce placental blood flow[85,86]
- hypothermia shifts the maternal haemoglobin–oxygen dissociation curve to the left, reducing placental gas exchange
- maternal acid–base disturbances can further compromise the fetus, and temperature should be taken into consideration in the interpretation of arterial blood gases
- hypothermic cardiopulmonary bypass (CPB) may be associated with higher fetal mortality than normothermic CPB.[87]

Fetal bradycardia may be associated with fetal distress or hypothermia.[88] Increasing maternal Pa_{O_2} may attenuate fetal bradycardia; however, hyperoxia post cardiac arrest has been found to be associated with increased mortality, possibly due to increased reactive oxygen species in the context of ischaemia–reperfusion injury.[89]

Fetal bradycardia with heart rates around 90–100 beats per minute were reported in the case of successful TH in pregnancy.[83]

Maternal hypothermia and alkalaemia decrease fetal Pa_{O_2}.[90] Maternal Pa_{CO_2} and pH should ideally be maintained at values normal for gestation. By 12 weeks' gestation, maternal Pa_{CO_2} is normally around 32 mmHg (4.25 kPa) with pH 7.44. Fetal pH is normally around 0.1 less than maternal. In the TH range of 32–34°C, corrected values can be estimated by the subtraction

of 5 mmHg (0.66 kPa) per 1°C below 37°C for Pa_{O_2}, subtraction of 2 mmHg (0.27 kPa) per 1°C below 37°C for Pa_{CO_2}, and addition of 0.012 per 1°C below 37 °C for pH.[36,39] Although an alpha-stat approach is generally recommended during hypothermic cardiopulmonary bypass in pregnancy, the best approach is uncertain.[86,91]

SEDATION, PARALYSIS AND SEIZURES

Seizures occur in around 36% of patients after ROSC, mostly within the first 24 hours (and therefore coinciding with the period of TH[92,93]) and can result in further brain injury in as little as 30 minutes.[92–95]

The use of paralysis to control shivering during TH may mask seizure activity, and electroencephalographic (EEG) monitoring should be considered in paralysed patients.[96] However, it is not known whether the treatment of seizures impacts patient outcome post cardiac arrest and therefore a strong recommendation for EEG monitoring and aggressive attempts to control seizure activity cannot be made at this stage.[97]

NEUROLOGICAL OUTCOME AND PROGNOSTICATION FOLLOWING TH

There is considerable uncertainty about the effect of TH on the reliability of clinical signs as predictors of poor neurological outcome following cardiac arrest. New data suggest that the 2006 American Academy of Neurology (AAN) guidelines for neurological prognostication following cardiac arrest do not have the same degree of accuracy in patients treated with TH.[45,98,99]

The current level of evidence is considered inadequate to support a specific method of determining poor neurological prognosis with certainty.[45]

Electrical Safety and Injuries

Lester AH Critchley

Patients suffering from the consequences of electrocution and associated burns occasionally require ICU management. Patterns of presentation include post cardiopulmonary arrest, coma, blunt trauma and severe burns – either direct or indirect from electrical arcs, flashes or fires. An understanding of the physical concepts behind electrical power supplies and how electrocution occurs helps in determining the extent of these injuries.

Patients and staff in the ICU are at risk of electrocution from faulty electrical equipment. The necessity of direct patient contact with electrical equipment increases this risk, and when therapy involves an invasive contact close to the heart, microshock is an additional hazard. Thus, strict adherence to internationally accepted electrical safety standards is desirable. Faulty electrical equipment can also result in power failures, fires and explosions. The use of mobile phones and related devices near patient equipment can lead to malfunctioning.

PHYSICAL CONCEPTS

Electricity is produced by the movement of negatively charged electrons. A *potential difference* or voltage, measured in volts (V), exists between two points if the number or density of electrons is greater at one point. When these points are connected by a conductor, the potential difference will cause electrons or an *electric current* (I), measured in amperes (A), to flow. *Resistance* (R), measured in ohms (Ω), opposes this flow of electrons. Resistance is low in a conductor, because electrons can move freely from atom to atom. However, resistance is high in an insulator as electrons are unable to move freely. Voltage, current and resistance are related by Ohm's law:

$$V = I \times R \tag{83.1}$$

If an electric current flows through a resistance, it dissipates energy as heat. The heating effect per second, or *power*, is measured in joules (J)/s or watts (W):

$$\text{power} = V \times I = I^2 \times R \tag{83.2}$$

A current that flows in one direction, such as produced by a battery, is called a *direct current*. Electricity to homes, hospitals, and factories is supplied as an *alternating current*, which flows back and forth at a *frequency* (i.e. cycles per second or hertz (Hz)). Voltage and frequency specifications vary worldwide. This may cause problems when electrical equipment designed to be used in one region is used elsewhere. Voltage specifications range from 100 V (i.e. Japan) to 240 V (i.e. Australia) with 220 V being most commonly supplied (i.e. Britain, most of Europe and Asia). The frequency most commonly supplied is 50 Hz. North America is a notable exception, where the specification is 110–120 V and 60 Hz.

For efficiency, electricity is distributed from the power station using ultra-high voltages. Main power-grids carry >1 million volts, which is stepped down by transformers to >10 000 V to supply local power-lines, that are further stepped down to 120 to 220 V for domestic, commercial and factory use. Accidental contact with these high-voltage supply lines can be fatal if the current returns to ground with the person in its path. High-voltage currents can also flow via ionised air. This is known as electrical arcing and causes surface or flash burns. If an electrical fault occurs in domestic or hospital equipment, the flow of electricity can be re-routed to ground though a bystander who makes contact, resulting in electrocution.

A current flowing in a circuit produces electric and magnetic fields, which induce currents to flow in neighbouring circuits. When this results in a current flowing between the two circuits, it is called coupling. With *capacitive coupling*, high-frequency currents are most easily passed, and the size of the current is greatest when the circuits are in close proximity. *Inductive coupling* can result from the strong magnetic fields produced by heavy-duty electrical equipment such as transformers, electric motors, and magnetic resonance imaging (MRI) machines. The most common problem associated with coupling is electrical interference or 'noise'. Monitoring equipment is designed to 'filter' out this noise. However, in certain circumstances, such as the use of high-frequency surgical diathermy and magnetic resonance, sufficient amperage can be induced to cause microshock and burns.[1,2] Smaller electromagnetic fields emitted by hand-held devices, such as mobile phones, can affect the programming of microprocessors. Cases of patient equipment malfunctions have been reported.[3]

Static electricity has no free flow of electrons. Insulated objects can become highly charged, usually by repeated rubbing. The charge is dissipated by electrons jumping onto another neighbouring object of a different potential. 'Jumping' electrons ionise and heat the air through which they pass, causing a spark, which may ignite an inflammable liquid or gas. Lightning is a type of static electrical discharge. Direct currents of 12 000–200 000 A and voltages in the millions are involved; however, flow lasts for only a fraction of a second.[4]

ELECTROPHYSIOLOGICAL CONSIDERATIONS

For a current to flow through the body, the body must complete a circuit. Usually this involves the current flowing from its source to ground through the body, often hand to hand or hand to feet. The pathophysiological effects depend on the size and duration of the current, and this depends on the voltage and electrical resistance of the body. The main pathophysiological effects of current passing through the body are: (i) ventricular fibrillation or asystole, (ii) sustained muscle contraction or tetany causing the 'cannot let go' phenomenon and asphyxiation, and (iii) dissipation of electrical energy as heat causing burns, often to deep-seated structures as well as skin. Muscle, blood vessels and nerves act as the main conduits for currents flowing through the body, and offer a very low resistance 500–1000 Ω.[9] Most of the resistance to passage of the current, and thus burning effect, occurs at the skin contact, which can vary enormously. Dry skin has a resistance in excess of 100 000 Ω.[5] However, skin resistance is markedly reduced (to 1000 Ω)[6] if the skin is wet, or if a conductive jelly has been applied. Hence, from Ohm's law, dry skin in contact with 240 V mains supply will result in a harmless 0.24 mA current flowing through the body, whereas moist or wet skin will result in a potentially lethal 240 mA current.

ELECTROCUTION

EPIDEMIOLOGY

Most cases of electrocution occur either in the workplace (about 60%) or at home (about 30%).[6] Most data on the incidence of electrocution come from North America, though significant regional differences exist worldwide. Children under 6 years are most at risk from domestic electrocution, but with greater electrical safety awareness and the use of ground fault circuit interrupters (GFCIs), the oral burns once seen from chewing power cords are much less common.[7] Young adult Caucasian men are the most likely victims of electrocution in the workplace. Power-lines and electrified railway tracks are the most common causes of high-voltage injuries.

CAUSES AND PATTERNS

There are a number of causes of electrocution and each has its own pattern of injuries:

1. *Low-voltage alternating current (AC) with or without loss of consciousness or arrest:* these injuries usually involve exposure to <1000 V in the home or office setting
2. *High-voltage AC with or without loss of consciousness or arrest:* these injuries can cause extensive thermal burns and usually are occupation related
3. *Direct current (DC) injury:* these injuries often involve trauma due to the victim being thrown due to violent muscle contraction
4. *Conducted electrical weapons (CEWs) such as Tazers used by the police:* CEWs deliver high-voltage currents, either AC or pulses of DC in the order of 50,000 V. Injuries are due mainly to trauma secondary to the Tazer shock[8]
5. *Lightening strike:* this is discussed later.

PATHOPHYSIOLOGY

Pathophysiological processes involved in electrical injuries from an electrical engineer's perspective are well described in a short review article by Bernstein.[9] The extent of injury depends on: (i) the amount of current that passes through the body, (ii) the duration of the current, and (iii) the tissues traversed by the current (**Table 83.1**). The extent of injury is most directly related to amperage. However, usually only the voltage involved is known. In general, lower voltages cause less

Table 83.1 Origin and pathophysiological effects of different levels of electrical injury

CURRENT (A)	SOURCE	EFFECTS ON VICTIM
10–100 μA	Earth leakage	Microshock (ventricular fibrillation)
300–400 μA	Faulty equipment	Tingling (harmless)
>1 mA	Faulty equipment	Pain (withdraw)
>10 mA	Faulty equipment	Tetany (cannot let go)
>100 mA	Faulty equipment	Macroshock (ventricular fibrillation)
>1 A	Faulty equipment	Burns and tissue damage
>1000 A	High-tension injury	Severe burns and loss of limbs
>12 000 A	Lightning	Coma, severe burns and loss of limbs

injury, although voltages as low as 50 V have caused fatalities.

TISSUE HEAT INJURY

Currents in excess of 1 A generate sufficient heat energy to cause burns to the skin at entrance and grounding points and occult thermal injury to internal tissues and organs. Small blood vessels and nervous tissue appear to be particularly susceptible.[6]

DEPOLARISATION OF MUSCLE CELLS

An alternating current of 30–200 mA will cause ventricular fibrillation.[10] Domestic frequencies of 50–60 Hz are most dangerous, being three times more likely to stop the heart than direct or high-frequency current sources. Currents in excess of 5 A cause sustained cardiac asystole, which is the principle used in defibrillation. Apart from ventricular fibrillation, other arrhythmias may occur. Myocardial damage is common and may result in ST and T-wave changes. Global left ventricular dysfunction may occur hours or days later, despite initial minimal ECG changes.[11,12] Myocardial infarction has also been reported.[13] Specific markers of myocardial injury, such as cardiac troponin, should be checked in all suspected cases of electrical injury to the heart.[14]

Tetanic contractions of skeletal muscle occur with currents in excess of 15–20 mA. The threshold is particularly low with alternating currents at the household frequency of 50–60 Hz. Tetanic contraction will prevent voluntary release of the source of electrocution, the 'cannot let go' phenomenon, and violent muscle contractions may cause fractures of long bones and spinal vertebrae.[6]

VASCULAR INJURIES

Blood vessels may become thrombosed and occluded as a result of the thermal injury. Small vessels are at greater risk as the blood flow in larger vessels dissipates the heat. Compartment syndromes are seen secondary to tissue oedema, causing tissue ischaemia and necrosis. Affected limbs may require fasciotomy and amputation.[15]

NEUROLOGICAL INJURIES

Neurological injuries may be central or peripheral, and immediate or late in onset. Unconsciousness following electrocution may result from cardiorespiratory arrest, trauma to the head or the direct effect of current passing through the brain. This may be one of the main reasons for admission to ICU. Monoparesis may occur in affected limbs, and the median nerve is particularly vulnerable.[6,16] Monoparesis may be due to the direct effect of electricity passing through the body or delayed effect due to scar formation. Electrocution to the head may result in unconsciousness, paralysis of the respiratory centre, and late complications such as epilepsy, encephalopathy and Parkinsonism.[6,16] Spinal cord damage resulting in para- or tetraplegia can result from a current traversing both arms and the spine.[6,16] Autonomic dysfunction may also occur causing acute vasospasm or a late sympathetic dystrophy.[6]

RENAL FAILURE

Direct electrical injury to the kidneys is unusual. However, acute renal failure may result from the myoglobinuria and toxins produced by extensive muscle necrosis.[16]

EXTERNAL BURNS

Victims of high-voltage electrocution can incur extensive superficial or deep external burns from electrical arcs passing over the skin surface, fires especially from clothes catching fire and heated metal objects such as jewellery. Arc formation requires voltages in excess of 350 V and tracks over the body surface. They can generate extremely high temperatures of up to 5000°C that mainly cause skin burns.[9] Victims can also be burnt by the intense flash caused by the electrical discharge.

OTHER INJURIES

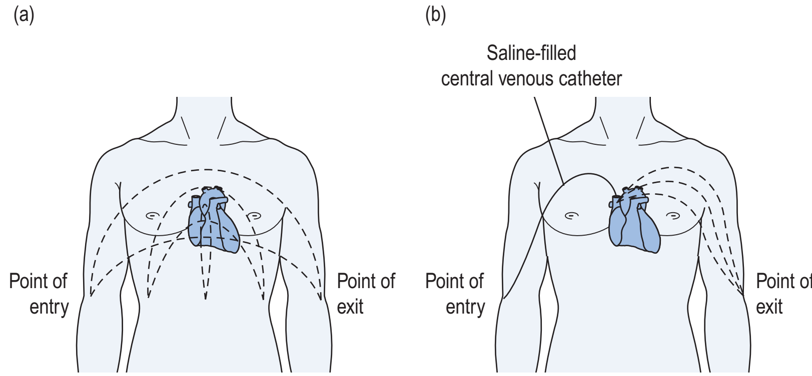
High-voltage and direct current electrocution can cause the victim to fall or be thrown, which may result in traumatic blunt injuries. Thus, it is important to get a reliable witness report of the incidence so that the nature of the patients' injuries is properly understood and nothing is missed, like a fractured cervical spine. All unconscious electrocuted patients should be initially treated with neck and spinal protection. High-voltage injuries can commonly rupture the eardrum and affect hearing.[17] Cataracts may later develop.[18]

MACRO- AND MICROSHOCK

The above domestic/workplace electrocution is known as *macroshock*, and occurs when current flows through the intact skin and body.

In the ICU and other high-level patient care areas, the potential for *microshock* electrocution also exists. Microshock occurs when there is a direct current path to the heart muscle that bypasses the protective electrical resistance of the skin surface. Such a pathway may be provided by saline-filled arterial or venous-pressure-monitoring catheters or transvenous pacemaker wires. The current required to produce ventricular fibrillation in microshock settings is extremely small, in the order of 60 μA.[15] Currents of 1–2 mA are barely perceptible and produce tingling of the skin (see Table 83.1). Hence a lethal microshock may be transmitted to a patient via

Figure 83.1 Microshock: (a) low current density at the heart; (b) high current density at the heart if there is a conducting pathway, such as a saline-filled catheter.



a staff member who is unaware of the conducted current. Microshock can result from direct contact with faulty electrical equipment, or stray currents from capacitive coupling, or earth leakage. Such small currents are potentially lethal because a high current density is produced at the heart (**Fig. 83.1**). Patients at risk of microshock require higher levels of electrical safety protection.

HIGH-TENSION AND LIGHTNING STRIKE INJURIES

High-tension electricity (>1000 V) involves voltage much greater than domestic supply, usually many thousands of volts. Sources include power-lines, electrified railway tracks and equipment requiring high internal voltages produced by step-up transformers, such as televisions. Tissue damage is mainly due to the generation of heat, as high-amperage currents are involved. Not only does the current pass through the victim, but electrical arcing may also be involved. Witnesses have described tissues actually exploding.[19]

Lightning injury is a type of high-tension injury. Its incidence depends upon geographical location. Generation of lightning is surprisingly complex and involves a number of steps. The victim of a lightning strike may be hit directly, injured by the side-flash from a nearby object, or electrocuted by ground currents which re-route through the victim's legs.[9]

Victims can be thrown several feet as a result of violent muscular contractions. Electrical arcing of the air causes intense heat, resulting in superficial burns and the clothes igniting. Characteristic entrance and exit site burns are seen, which have a spider-like appearance with redness and blistering. Victims are usually unconscious in the initial phase. However, many victims survive (80–90%),[4] and good recovery has been reported despite initial hopeless neurological responsiveness (e.g. fixed dilated pupils).[20] Immediate death usually results from cardiorespiratory arrest; asystole is more common than ventricular fibrillation.[4]

MANAGEMENT OF ELECTRICAL INJURIES

Treatment of electrical injuries is mainly supportive. It includes the following.

FIRST AID AND RESUSCITATION

It is imperative to make the immediate environment safe for rescuers. Power sources should be switched off and wet areas avoided where possible. Instinctive attempts to grab the electrocuted victim must be avoided until it is safe to do so. Cardiopulmonary resuscitation is carried out when indicated, and continued even if the prognosis seems hopeless. The neck and spine should be protected because of possible fractures.

INVESTIGATIONS

Investigations are indicated to detect damaged organs. They include electrocardiogram (ECG), echocardiography, computed tomography (CT) of the head, EEG, X-rays of the spine and long bones, haemoglobin, serum electrolytes, creatinine kinase and urine myoglobin to assess muscle damage, and nerve conduction studies. Arteriograms may help in the decision to amputate a limb.[15]

HOSPITAL AND ICU MANAGEMENT

Management is directed towards treatment of burns, ischaemic and necrotic tissue, and injured organs. The principle of treating electrical burns is complete excision because of the risks of acute renal failure and sepsis. Fasciotomies and amputations may be necessary. Tetanus toxoid and antibiotics, especially penicillin, are given if indicated.

ELECTRICAL HAZARDS IN THE ICU

The ICU has the potential to inflict both macroshock and microshock injuries to staff and patients. Potential sources of these electrical hazards are:

MAJOR ELECTRICAL FAULTS

The casing and insulated wiring of electrical equipment protect against electric shock. Faulty wiring or components, and deterioration of internal insulation, can result in the casing becoming 'live'. Contact with live casing or wires can result in an electric current flowing through the victim to ground. The outcome largely depends on the resistance offered by the body to the current. If it is low, such as in a wet environment, sufficient current can flow to cause death, which is usually due to ventricular fibrillation/asystole or asphyxia from tetanic contraction of respiratory muscles.

MICROSHOCK CURRENTS

EARTH LEAKAGE CURRENTS

Within all pieces of electrical equipment, stray low-amperage electrical currents exist that usually flow to earth, called earth leakage currents. They originate from current leaks across imperfect insulation of wires, capacitive and inductive coupling within the equipment, and coupling from electric and magnetic fields that exist in the working environment, such as the 50–60 Hz mains supply. Normally these currents are small and harmless, but they have the potential to cause microshock.

PACING WIRES AND CENTRAL VENOUS LINES

In certain circumstances, sufficient current to cause microshock can be passed by capacitive and inductive coupling to intracardiac pacing wires and central venous lines. Ventricular fibrillation has been reported from capacitive coupling with thermistor wires in a pulmonary artery catheter.[1]

DIFFERENT EARTH POTENTIALS

Inadequate or faulty earthing can result in separate earthing points being at different resting potentials. If contact is made between the two earthing points, sufficient current can flow to cause microshock.

STAFF–PATIENT CONTACT

Small currents capable of causing microshock can be transmitted unknowingly to a patient by a staff member who simultaneously touches faulty electrical equipment and the patient. If this current returns to earth via an intracardiac connection, a high current density will pass through the heart, resulting in microshock.

INDUCTIVE CURRENTS

Inductive coupling from the strong magnetic fields produced by MRI can cause overheating of wires and equipment. Severe burns have resulted from the use of pulse oximetry during magnetic resonance imaging, and specially designed wiring and probes are recommended.[2] Similar problems can exist with any intravascular device containing wires, such as a pulmonary artery catheter. More recently problems have arisen from the interference caused by personal computers, mobile phones and related devices with patient equipment. Many hospitals have banned the use of such devices in areas where patients are treated.

OTHER RELATED HAZARDS

Electrical equipment has the potential to cause other hazards such as thermal injury, fire and power failures. Preliminary critical incident reports suggest that power failures are the most commonly encountered incidents involving electricity in the ICU. Power failures can be disastrous, as many patients' lives depend on electrically driven 'life support' equipment. As the intensivist frequently works outside the ICU, they should also be aware of potential electrical hazards outside ICU.

MEASURES TO PROTECT STAFF AND PATIENTS

EARTHING, FUSES AND CIRCUIT BREAKERS

Earthing reduces the risk of macroshock. The casing in most electrical equipment is connected to ground by a very-low-resistance wire called the earth, which uses the third pin of the electrical socket. If a fault arises, the earth wire offers a low-resistance path to ground. The high-amperage current that results will blow the main fuse or circuit breaker, thus providing protection and warning that a fault is present. However, fuses and circuit breaker do not guarantee patient protection from macroshock and other more sensitive protection strategies are required in patient care locations (see below). Additional protection can be achieved by connecting all the earthing points in a patient care area together by a very-low-resistance wire. This reduces the risk of microshock occurring from earthing points at different potentials, and is commonly used in cardiac protected areas.

ISOLATED POWER SYSTEMS (IPS)

MAINS ISOLATION

The power supply is isolated from earth using a mains isolation transformer. If contact is made with live faulty circuitry, the risk of electric shock is reduced because stray currents no longer preferentially flow through patient or staff member to earth. Presence of stray earth leakage currents can be detected by using a line isolation monitor. This type of system is particularly useful in wet locations where the body may offer a very low resistance to earth.

INTERNAL ISOLATION

In medical equipment the mains power supply is usually isolated from the patient connection by using internal transformers and photoelectric diodes. The casing is still earthed to protect against faulty circuitry.

This method of protection is commonly used in ICU equipment, including most monitoring and patient information systems. Electrical power isolation may limit the use of networks that link patient monitors to printers and information technology systems.

GROUND FAULT CIRCUIT INTERRUPTERS (GFCIs)

Ground fault circuit interrupters are devices that switch off the electrical supply if small currents are detected flowing to earth. GFCIs are designed to protect against electrocution from faulty electrical equipment. They are commonly incorporated into electrical sockets and require activation. When contact is made with the faulty equipment an increased current will flow to earth, which trips the system. GFCIs also protect against microshock. A major concern with using GFCIs in critical patient management areas, however, is that power supply to essential life-supporting equipment such as heart–lung machines can be permanently switched off by small-leakage currents.

ELECTRICAL SAFETY STANDARDS

Most First-World nations have standards of electrical safety that apply to both the design of medical equipment and their use in healthcare locations. A number of well-recognised standards exist that can be easily found and uploaded from the internet. The US follows the National Electric Code, which has a section on Health Care Locations and was most recently updated in 2011. Europe and Great Britain follow the International Electrotechnical Commission Code IEC 60601, first published in 1997 and regularly updated, most recently in 2011. IEC 60601-1 is widely accepted as the benchmark for medical equipment and has become the de facto requirement for medical equipment worldwide. Australia and New Zealand follow similar standards (AS/NZS 3003:2011 and AS/NZS 3200:2010). Hospitals worldwide should establish their own committees to ensure that these standards are applied.

Patient care areas differ in their safety requirements and commonly used classifications are listed below. The ICU should conform to 1(b) and preferably 1(c), as follows:

1. **a.** Unprotected areas, where only routine electrical safety standards are applied
   b. Body-protected areas, where the level of electrical safety is sufficient to minimise the risk of macroshock when the patient is in direct contact with electrical equipment and the skin impedance is reduced or bypassed
   c. Cardiac-protected areas, where the level of electrical safety is sufficient to minimise the risk of direct microshock to the heart
2. Wet locations, where spillage of water and physiological solutions, such as saline and blood, frequently occurs; the US Department of Defense until recently defined wet areas as those used for cystoscopy, arthroscopy and labour/delivery[23]
3. In the past, standards existed for the safe use of inflammable anaesthetic agents.

Currently, the US only requires GFCIs in wet areas that do not include ICUs and most operating theatres. Other countries, such as Australia, New Zealand and Great Britain require IPSs in operating rooms and ICUs. If cost is not an issue, ideally both internal isolation and GFCIs should be used in 1(a) and 1(b) and wet locations. More stringent controls to protect against microshock are required in 1(c) cardiac-protected locations.

EQUIPMENT CHECKS

The purchase of new equipment should be strictly controlled, and circuit diagrams should be provided. All new equipment should be checked that it adheres to the appropriate electrical safety standards, functions properly and for current leaks before it is used in the ICU or other high-risk patient areas. Preventative maintenance of equipment should be done regularly. Dated stickers should be used to show when the equipment was last checked. All faulty equipment must be removed from service, labelled appropriately and recommissioned only after thorough checking.

RESERVE POWER SUPPLIES AND ALARMS

All essential equipment should have a reserve power supply (usually a battery), and alarms that warn of power failure. All hospitals should provide an emergency backup power supply in case of power cuts. Protocol should be in place, or developed, to ensure continuation of ventilation, sedation and other essential life-sustaining therapies in case of complete electrical power failure, or the need to evacuate patients because of fire.

PERSONNEL EDUCATION

Staff should be taught correct ways to handle electrical equipment. Equipment with frayed wires should never be used, plugs should never be tugged, trolleys should never be wheeled over power cords, and two pieces of equipment should never be handled simultaneously. Staff should also respond appropriately to alarms. The increasing use of patient monitoring and information technology systems means that an increasing number of electrical devices are being used at any one time at the patient's bedside, with increasing need for power cords and sockets. Care should be taken when using multiple socket power cables to ensure that their use does not violate electrical safety standards.

Envenomation

James Tibballs

Envenomation by snakes, spiders, ticks, bees, ants, wasps, jellyfish, octopuses or cone shell snails may threaten life, while envenomation by other creatures may cause serious illness.[1] Although this chapter focuses on management of envenomation in Australia, the principles of management are widely applicable in other countries. Immediate advice on management may be obtained from the Australian Venom Research Unit (AVRU) advisory service on its 24-hour telephone number within Australia on 1300 760 451, from overseas on +61 3 8344 7753 or from their website at http://www.avru.org.

SNAKES

EPIDEMIOLOGY

Australia is habitat to a large number of venomous terrestrial and marine snakes (Families Elapidae and Hydrophiidae). The genera responsible for the majority of serious illness are Brown Snakes (*Pseudonaja*), Tiger Snakes (*Notechis*), Taipans (*Oxyuranus*), Black Snakes (*Pseudechis*) and Death Adders (*Acanthophis*). Each genus comprises several or many species.

The mean snake bite death rate in Australia from 1982 to 2011 was 2.1 per year (~0.01/100 000) (Ken Winkel, personnal communication), usually occurring because of massive envenomation, snake bite in remote locations, rapid collapse, or delayed or inadequate antivenom therapy. However, as many as 2000 people are bitten each year and, of these, at least 300 require antivenom treatment. This morbidity and mortality is far less than that observed in India, South-East Asia and Africa. Death and critical illness is due to (1) progressive paralysis leading to respiratory failure, (2) haemorrhage, or (3) renal failure or combinations. Renal failure occurs as a consequence of rhabdomyolysis, disseminated intravascular coagulation (DIC), haemorrhage, haemolysis or to their combinations.

Snake bite is often 'accidental' when a snake is trodden upon or suddenly disturbed. However, many bites occur when humans deliberately interfere with snakes or handle them. At special risk are herpetologists and snake collectors who not only invariably sustain bites in the course of their work[2] or hobby, but also develop allergy to venoms and to the antivenoms used in their treatment. Contact with exotic snakes has additional problems.

SNAKE VENOMS

Venoms are complex mixtures of toxins, usually proteins, which kill the snake's prey and aid its digestion. Many toxins are phospholipases. The main toxins cause paralysis, coagulopathy, rhabdomyolysis and haemolysis (**Box 84.1**). Coagulopathy is due either to the procoagulant effect of prothrombin activators (factor Xa-like enzymes), with consumption of clotting factors and possible thrombotic sequelae such as thrombotic microangiopathic renal failure,[3] or to a direct anticoagulant effect. Platelets may be consumed and fibrinolysis may occur as a secondary phenomenon resembling the findings in disseminated intravascular coagulation (DIC) caused by other conditions. When circulating venom has been neutralised by antivenom, it may be 4–6 hours or longer before hepatic manufacture of clotting factors can normalise coagulation tests.

SNAKE BITE AND ENVENOMATION

Although a bite may be observed, envenomation may not occur because no venom or a small amount of venom is injected. Bites by Australian snakes are relatively painless and may be unnoticed. This is in marked contrast to bites of many overseas crotalid and viperid snakes, where massive local reaction and necrosis are caused by proteolytic enzymes. In general, Australian snake venoms do not cause extensive damage to local tissues and are usually confined to mild swelling and bruising, and continued slight bleeding from the bite site. After Australian snake bite, paired fang marks are often visible but sometimes only scratches or single puncture wounds exist.

SYMPTOMS AND SIGNS OF ENVENOMATION

Classical symptoms and signs are given in **Box 84.2**. Sometimes, not all possible symptoms and signs occur. In some cases one symptom or sign may dominate the clinical picture, and in other cases they may wax and wane. These phenomena may be explained by

Box 84.1 Main components of Australian snake venoms

Neurotoxins
Presynaptic and postsynaptic neuromuscular blockers present in all dangerous venomous snakes. Cause paralysis
Postsynaptic blockers readily reversed by antivenom
Presynaptic blockers are more difficult to reverse, particularly if treatment is delayed
Some presynaptic blockers are also rhabdomyolysins

Prothrombin activators
Present in many important species
Cause consumption coagulopathy and possibly thrombotic microangiopathy (disseminated intravascular coagulation)
Intrinsic fibrin(ogen)lysis generates fibrin(ogen) degradation products
Significant risk of haemorrhage

Anticoagulants
Present in a relatively small number of dangerous species
Prevent blood clotting without consumption of clotting factors

Rhabdomyolysins
Some presynaptic neurotoxins also cause lysis of skeletal and cardiac muscle
Apart from loss muscle of mass, may cause myoglobinuria and renal failure

Haemolysins
Present in a few species
Rarely a serious clinical effect

Box 84.2 Progressive onset of major systemic symptoms and signs of untreated envenomation*

<1 hour after bite
Headache
Nausea, vomiting, abdominal pain
Transient hypotension associated with confusion or loss of consciousness
Coagulopathy (laboratory testing)
Regional lymphadenitis

1–3 hours after bite
Paresis/paralysis of cranial nerves (e.g. ptosis, double vision, external ophthalmoplegia, dysphonia, dysphagia, myopathic facies)
Haemorrhage from mucosal surfaces and needle punctures
Tachycardia, hypotension
Tachypnoea, shallow tidal volume

>3 hours after bite
Paresis/paralysis of truncal and limb muscles
Paresis/paralysis of respiratory muscles (respiratory failure)
Peripheral circulatory failure (shock), hypoxaemia, cyanosis
Rhabdomyolysis
Dark urine (due to myoglobinuria or haemoglobin)
Renal failure

*In massive envenomation or in a child, a critical illness may develop in minutes rather than hours.

variations in toxin content of venoms of the same species in different geographical areas, and by variable absorption of different toxins.

The cause of transient or prolonged hypotension soon after envenomation is obscure but it may be related to intravascular coagulation with myocardial ischaemia and pulmonary hypertension culminating in systemic hypotension.[4,5] Prothrombin activators gain access to the circulation within a number of minutes after subcutaneous injection. Tachycardia and relatively minor ECG abnormalities are common. Other causes of hypotension such as direct cardiac toxicity are possible.

Tender or even painful regional lymph nodes are moderately common but are not per se an indication for antivenom therapy. Lymphadenitis also occurs with bites by mildly venomous snakes that do not cause serious systemic illness.

Occasionally intracranial haemorrhage occurs. In the case of untreated or massive envenomation, rhabdomyolysis may occur. This usually involves all skeletal musculature and sometimes cardiac muscle. The resultant myoglobinuria may cause renal failure.

A high intake of alcohol by adults before snake bite is common, and may confound the cluster of symptoms and signs. Pre-existing treatment with anticoagulant (e.g. warfarin) or disease (e.g. gastrointestinal tract ulceration) may complicate management of coagulopathy.

SNAKE BITE IN CHILDREN

Snake bite in young children presents additional problems. Envenomation is difficult to diagnose when a bite has not been observed. The symptoms of early envenomation may pass unsuspected and the signs, particularly cranial nerve effects, are difficult to elicit. Bite marks may be difficult to distinguish from the effects of everyday minor trauma. Lastly, the onset of the syndrome of envenomation is likely to be more rapid and severe because of the relatively higher ratio of venom to body mass. Presentation may be cardiorespiratory failure.

IDENTIFICATION OF THE SNAKE

Identification of the snake is helpful but not essential since a venom detection kit test is available for snakes of Australia and Papua New Guinea. If the snake cannot be identified, a specific monovalent antivenom, or a combination of monovalent antivenoms or polyvalent antivenom should be administered on a geographical basis. Nevertheless, identification guides selection of the appropriate antivenom, and provides an insight into the expected syndrome. Administration of the wrong antivenom may endanger a victim's life because

a generic monovalent antivenom (e.g. Brown Snake antivenom) does not neutralise venoms of other genera (e.g. Tiger Snakes, Taipans).

Identification by venom detection kit test

The venom detection kit (VDK) is an in vitro test for detection and identification of snake venom at the bite site, in urine, blood or other tissue in cases of snake bite. It can be performed at the bedside or in the laboratory. It is an enzyme immunoassay using rabbit antibodies and chromogen and peroxide solutions. A positive result will indicate the type of antivenom to be administered. It detects venom from a range of snake genera including Tiger, Brown, Black, Death Adder and Taipan. Individual species of snake cannot be identified by the test and several genera may yield a positive result in a specified well. The test is very sensitive, able to detect venom in concentrations as low as 10 ng/mL, and can yield a visual qualitative result in test wells in approximately 25 minutes. The incidences of false-positive and false-negative tests of the kit are low. On occasions, venom may be detected but the patient is asymptomatic and has no signs of envenomation. A decision to administer antivenom should be made on clinical grounds. A very high concentration of venom in a sample may overwhelm the test and yield a spuriously negative result (Hook effect). If that possibility exists, a diluted sample should be retested.

Identification by physical characteristics

This can be misleading. Not all brown-coloured snakes are Brown Snakes, not all black-coloured snakes are Black Snakes and not all banded snakes are Tiger Snakes. Moreover, Brown Snakes may have bands and Tiger Snakes may lack characteristic bands. Non-herpetologists should consult an identification guide[1] with reference to scale patterns to identify a specimen correctly if antivenom therapy is to be based on morphological characteristics alone.

Identification by clinical effects

The appearance of a bite site cannot be used to reliably identify a snake. The constellation of symptoms and signs may be useful to a limited degree. For example, paralysis associated with procoagulopathy may be caused by a Tiger, Taipan, Brown, or Rough-scaled Snake, *Hoplocephalus* spp. or Red-bellied Black Snake, but if rhabdomyolysis also occurs a bite by a Brown Snake is improbable. Paralysis associated with anticoagulation may be caused by a Black Snake (other than a Red-bellied Black Snake), Copperhead or Death Adder, but if rhabdomyolysis occurs a bite by a Death Adder is improbable. Paralysis with neither coagulopathy nor rhabdomyolysis may be caused by a Death Adder bite.

This information is obviously of limited practical importance. It is essential to administer antivenom at the first opportunity when indicated, rather than wait until the full syndrome becomes apparent, to enable an 'educated clinical guess' in selection of the appropriate antivenom.

MANAGEMENT OF SNAKE ENVENOMATION

The essentials of management are:

- resuscitation – mechanical ventilation and restoration of blood pressure with intravenous fluids, inotropic and vasoactive agents as needed
- application of a pressure-immobilisation first-aid bandage
- administration of antivenom
- performance of investigations.

From a practical point of view, one of three clinical situations arises after snake bite. A plan of management for each of these is summarised in **Figure 84.1**:

- victim presents with a critical illness
- victim is envenomated but not critically ill
- victim is bitten but does not appear envenomated.

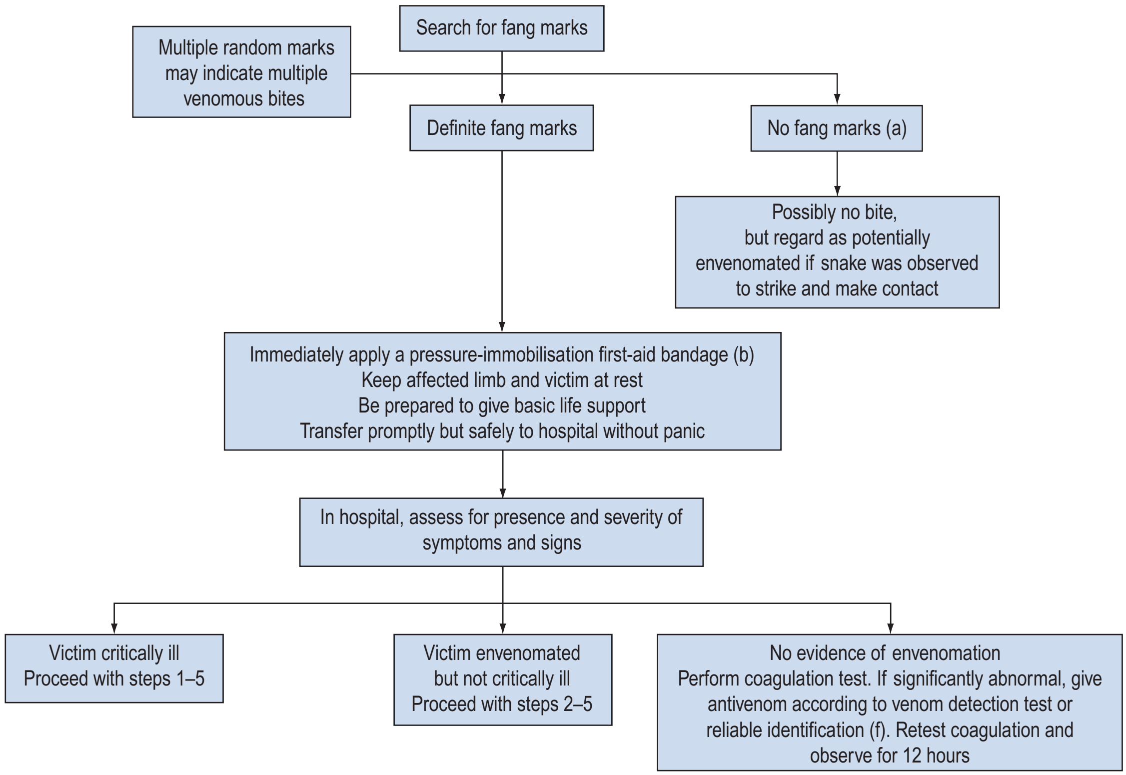
When the envenomated victim is not critically ill, time is available to identify the snake by investigations and to administer specific monovalent antivenom. A pressure-immobilisation bandage should be applied if not already in place, and not removed until antivenom has been administered.

When the victim has been bitten but not apparently envenomated, admission to hospital is advisable with observation and examination hourly for at least 12 hours in the case of a child but less time for an adult. The syndrome of envenomation may be very slow in onset over numerous hours with an initial period free of symptoms. A test of coagulation should always be performed. If a coagulopathy is present, specific monovalent antivenom should be administered after identification of the species or as indicated by a VDK test. If only a mild coagulopathy is present it may be acceptable to withhold antivenom in the anticipation of spontaneous resolution, but coagulation should be checked at intervals and the victim maintained under surveillance until coagulation is normal.

THE PRESSURE-IMMOBILISATION TECHNIQUE OF FIRST AID

Since at least 95% of snake bites occur on the arms or legs,[1] Sutherland's first-aid pressure-immobilisation technique[6] is applicable in the majority of cases. With this technique, a crêpe (or crêpe-like) bandage, but preferably elasticised, is applied from the fingers or toes up the limb as far as possible, encompassing the bite site. It should be as firm as required for a sprained ankle. Additional immobilisation is applied to the entire limb by a rigid splint, with the aim of immobilising the joints either side of the bite site.

Venom is usually deposited subcutaneously. The systemic spread of venom is largely dependent on its absorption by way of the lymphatics[7] or the small blood



1. Resuscitate (treat hypoxaemia and shock)
   Be prepared to intubate and mechanically ventilate. Admit to intensive care.
2. Apply pressure-immobilisation bandage. Do not remove if already applied [b]
3. Give antivenom intravenously [c,d,e,f,g]
   - Give monovalent if species reliably known or appropriate antivenom indicated by venom detection test.
   - In critically ill victim, don't wait for venom detection test result or if species cannot be determined; give according to geographic location:
     Victoria – Brown and Tiger Snake
     Tasmania – Tiger Snake
     Other states and territories – polyvalent
   - Titrate antivenom against clinical and coagulation status (NOTE: Death Adders don't cause significant coagulopathy).
4. Perform investigations
   - Bite swab for venom detection. (First-aid bandage may be cut to expose bite site, and then reinforced)
   - Blood for venom detection, coagulation, type and cross-match blood (if bleeding), fibrin degradation products, full blood examination, enzymes, electrolytes, urea, creatinine
   - Urine for venom detection, red blood cells, haemoglobin, myoglobin.
5. Examine frequently to detect slow onset of paralysis [h], coagulopathy, rhabdomyolysis and renal failure.

Dangers and mistakes in management

a. Fang marks not visible to naked eye.
b. Premature release of bandage may result in sudden systemic envenomation. Leave in situ until victim reaches full medical facilities. If clinically envenomated, remove only after antivenom given.
c. Erroneous identification of snake may cause wrong antivenom to be given. If in any doubt treat as unidentified.
d. Antivenom without premedication. Anaphylaxis is not rare and may not respond to treatment.
e. Insufficient antivenom. Titrate dose against clinical and coagulation status.
f. Blood and coagulation factors (fresh frozen plasma, cryoprecipitate) not preceded by antivenom will worsen coagulopathy.
g. Antivenom given without clinical or laboratory evidence of envenomation.
h. Delayed onset of paralysis may be missed. Victim must be examined at least hourly.

Figure 84.1 Management of snake bite.

vessels. Application of a pressure less than arterial to the bitten area when combined with immobilisation of the limb effectively delays the movement of venom to the central circulation.[6] Although it is a first-aid technique designed for use in the field, it should be part of initial management in hospital since it halts further absorption of venom. Some experimental and anecdotal evidence with Death Adder bites suggests that the technique inactivates some venom at the bite site,[1] but prolonged application has not been subjected to a controlled study.

Removal of the pressure-immobilisation bandage

Removal in the case of envenomation may precipitate a sudden elevation in blood concentration of venom and collapse of the victim. On the other hand, first aid has not been proven to inactivate venom in humans. Its removal therefore should be dictated by the circumstance. When an asymptomatic snake-bite victim reaches hospital with the recommended first-aid measures in place, these should not be disturbed until antivenom, appropriate staff and equipment have been assembled. If the victim is symptomatic and antivenom is indicated, the first-aid measures should not be removed until after antivenom has been administered, and reapplied if the victim's condition deteriorates. A swab of the bite site may be obtained by removing the splint temporarily and then cutting a window in the bandage. Thereafter the bandage should be made good and the splint reapplied.

ANTIVENOM

CSL Ltd (Parkville, Australia, +61 393891204) produces highly purified equine monovalent antivenoms against the venoms of the main terrestrial snakes, including Tiger Snake, Brown Snake, Black Snake, Death Adder and Taipan. A polyvalent antivenom – a mixture of aliquots of all of these – is also available. A sea-snake antivenom is also produced from horses immunised with Beaked Sea-Snake (*Enhydrina schistosa*) and Tiger Snake venom.

Antivenom should be administered according to the identity of the snake or if unknown or doubtful, according to the result of a VDK test (**Table 84.1**). If neither of these criteria can be fulfilled, and if the situation warrants immediate antivenom therapy, the geographical location may be used a guide, since the distribution of many species is known (**Table 84.2**). Polyvalent antivenom should not be used when a monovalent antivenom could be used appropriately. For bites by uncommon snakes, when antivenom is indicated, polyvalent antivenom or a monovalent antivenom as indicated by a VDK test should be chosen.

Table 84.1 Antivenom and initial dosages when snake identified

SNAKE	ANTIVENOM	DOSE (UNITS)
Common Brown Snake	Brown Snake	4000
Chappell Island Tiger Snake	Tiger Snake	12 000
Copperheads	Tiger Snake	3000–6000
Death Adders	Death Adder	6000
Dugite	Brown Snake	4000
Gwardar	Brown Snake	4000
Mulga (King Brown) Snake	Black Snake	18 000
Papuan Black Snake	Black Snake	18 000
Red-bellied Black Snake	Tiger Snake *or* Black Snake*	3000 18 000
Rough-scaled (Clarence River) Snake	Tiger Snake	3000
Sea-Snakes	Sea-Snake *or* Tiger Snake	1000 3000
Small-scaled (Fierce) Snake	Taipan	12 000
Taipans	Taipan	12 000
Tasmanian Tiger Snake	Tiger Snake	6000
Tiger Snake	Tiger Snake	3000

*Smaller protein mass Tiger Snake antivenom preferable.
Antivenom units per vial: Brown Snake 1000; Tiger Snake 3000; Black Snake 18 000; Taipan 12 000; Death Adder 6000; polyvalent 40 000. Note: (1) If the victim on presentation is critically ill, 2–3 times these amounts should be given initially; (2) additional antivenom may be required in the course of management since absorption of venom may be delayed.

Dose

One vial of specific antivenom neutralises in vitro the average yield on 'milking'– a process whereby venom is harvested by inducing the snake to bite through a latex membrane. If the amount of venom injected at a bite is greater than the average yield on milking, one vial of antivenom will not be adequate therapy. In severe cases of envenomation, a number of vials of antivenom will need to be administered. Absorption of venom from a bite site(s) is a continuing process.

The initial doses of antivenom are given in Tables 84.1 and 84.2. The need for subsequent doses should be guided by the clinical response. After bites by species with coagulopathic effects the victim's coagulation status is a useful but not definitive guide to whether more antivenom is required. In the absence of a rapid measurement of exogenous venom procoagulant in blood, it is difficult to determine whether continued coagulopathy after antivenom administration is due to unneutralised venom or to the fact that hepatic

Table 84.2 Antivenom and initial dosages when identity of snake uncertain

STATE	ANTIVENOM	DOSE (UNITS)
Tasmania	Tiger Snake	6000
Victoria	Tiger Snake *and* Brown Snake	3000 4000
New South Wales and ACT; Queensland; South Australia; Western Australia; Northern Territory	Polyvalent	40 000
Papua New Guinea	Polyvalent	40 000

Note: (1) If the victim on presentation is critically ill, 2–3 times these amounts should be given initially; (2) additional antivenom may be required in the course of management since absorption of venom may be delayed.

manufacture of consumed coagulation factors requires at least 6 hours.

The dose of antivenom required varies because the amount of venom injected cannot be determined, and snakes may bite multiple times. Moreover, victims may present late after envenomation when toxins have already become bound to target tissues and cannot be easily neutralised. Some victims in this circumstance have required mechanical ventilation for many weeks despite large amounts of appropriate antivenom. A child may require more antivenom than an adult envenomated by the same amount of venom, and a victim in poor general health will likewise require more. Finally, antivenoms are manufactured against specific species and may have less neutralising ability against different species of the same genus or against unrelated species, even when the antivenom chosen is nevertheless appropriate.

Administration

The decision to administer antivenom must be based on clinical criteria of envenomation, and not restricted to the result of a VDK test. A positive VDK test of a biological sample establishes the diagnosis of envenomation and the choice of antivenom, but does not imply that antivenom should or should not be given.

If the victim is significantly envenomated, antivenom must be administered as there is no other effective treatment. Antivenom may be withheld if envenomation is so mild that spontaneous recovery may occur or the consequences of antivenom administration are likely to outweigh the benefit to be gained (e.g. in a herpetologist who is mildly envenomated and known to have allergy to antivenom).

Snake antivenoms must be given by the intravenous route, or in dire circumstances if a vein cannot be cannulated then by the intraosseous route. The large volume of fluid and slow absorption render the intramuscular route useless in emergencies.

A test dose of antivenom to determine allergy should not be done. It is unreliable and a waste of precious time.

Premedication

Antivenom should be preceded by premedication with subcutaneous epinephrine (adrenaline), approximately 0.25 mg for an adult and 0.005–0.01 mg/kg for a child, at least 5–10 minutes before commencement of infusion. In the moribund or critically ill victim when it is essential to administer antivenom quickly, the epinephrine may be given intramuscularly or even intravenously in smaller doses. However, in general epinephrine is not recommended by either of those routes because of the risk of intracerebral haemorrhage due to the combination of possible epinephrine-induced hypertension and venom-induced coagulopathy. Although intracerebral haemorrhage has been recorded in the past in association with premedication, all such cases occurred after intravenous epinephrine, and none with subcutaneous epinephrine. On the other hand, the incidence of adverse reactions (8–13%) and occasional death after antivenom are sufficient to warrant premedication with epinephrine, which is the only medication proven effective in reducing the incidence of antivenom-induced reactions and their severity.[8]

It is not prudent to forgo premedication on the assumption that if anaphylaxis occurs it will be treatable. Iatrogenic anaphylaxis has a high mortality despite vigorous and expert resuscitation.[9] If an adverse reaction to the first vial of antivenom has not occurred, subsequent vials do not need to be preceded by epinephrine. The reaction rate to polyvalent antivenom is higher than to monovalent antivenoms and should not be used when a monovalent antivenom or combinations will suffice.

The antihistamine promethazine is ineffective in this setting[10] and contraindicated because it may cause obtundation and hypotension, both of which may exacerbate and confound a state of envenomation. Other drugs such as steroids and aminophylline are also not useful in preventing anaphylaxis because their actions, apart from being unproven, are too slow in onset, but steroids are useful for preventing serum sickness.

Infusion

The antivenom may be injected slowly into a running intravenous line or diluted in Hartmann's or other crystalloid solution in approximately 1 in 10 volumes in a burette and administered over 15–30 minutes if the situation is not critical. This method reduces the risk of an anaphylactoid reaction resulting from its binding with complement. For small children, if multiple vials are required, the dilution may be less to prevent excessive fluid administration. In emergencies the antivenom may be infused quickly in high concentration.

Adverse reactions

Antivenom infusion should be administered in a location equipped and staffed by personnel capable of managing anaphylaxis, which is discussed in detail in Chapter 66. Intramuscular epinephrine is the key treatment in a dose of approximately 0.25–1.00 mg for adults and 10 μg/kg for children. Antivenom therapy should be discontinued temporarily and restarted when the victim's condition is stable.

Lesser degrees of immediate adverse reaction restricted to headache, chest discomfort, fine rash, arthralgia, myalgia, nausea, abdominal pain, vomiting, and pyrexia may be managed by temporary cessation of infusion and administration of steroids and antihistamine before recommencement.

A delayed hypersensitivity reaction, serum sickness, should be anticipated and patients warned of the symptoms and signs, which usually appear several days to 2 weeks after antivenom administration. Severity may range from a faint rash and pyrexia to serious multisystem disease including lymphadenitis, polyarthralgia, urticaria, nephritis, neuropathy and vasculitis. The incidence of serum sickness appears to be greater with the use of multiple doses of monovalent antivenom and with polyvalent antivenom. Prophylactic treatment is a course of steroids (e.g. prednisolone 1 mg/kg per day for 5 days).

INVESTIGATIONS AND MONITORING

Tests should be performed regularly, interpreted quickly and treated promptly to counter venom effects and its complications. Serial coagulation tests and tests of renal function are especially important. Absorption of venom from the bite site is a continuing process that should be anticipated. Apart from regular monitoring of vital signs and oxygenation, the following are specifically needed.

Bite site

A swab for venom testing should be done. It has the highest likelihood of detecting venom provided the site has not been washed. The bite site may be squeezed to yield venom if it has been washed. A positive result identifies venom but does not prove envenomation.

Urine

Test the urine for venom that may be present when venom in blood has been bound by antivenom and is therefore undetectable. Urine should also be tested for blood and protein. If the urine is pigmented a distinction should be made between haemoglobinuria and myoglobinuria, which is impossible with simple ward tests. Urine output should be recorded.

Blood

- Coagulation tests should include prothrombin time, activated thromboplastin time, serum fibrinogen and fibrin degradation products.
- A full-blood examination and blood film for haemoglobin level, evidence of haemolysis and platelet count. A mild elevation in white cell count is expected.
- Electrolytes, urea, creatinine and creatine phosphokinase (isoenzymes and troponin are useful) to monitor rhabdomyolysis and possible renal compromise.

Electrocardiogram

Sinus tachycardia, ventricular ectopy and ST segment and T-wave changes are not uncommon. These effects may be the direct result of venom toxins or from electrolyte disturbances caused by rhabdomyolysis or renal failure.

SECONDARY MANAGEMENT

Coagulation factor and blood transfusion

Although coagulopathy often resolves after several doses of antivenom it does not restore coagulation per se – it permits newly released or manufactured coagulation factors to act unopposed by venom. If haemorrhage is occurring, or if coagulation is not restored after several doses of antivenom over several hours, it is prudent to administer fresh frozen plasma and to remeasure coagulation at intervals. Because regeneration of coagulation factors takes many hours, treatment of isolated coagulopathy entirely with antivenom while waiting for their regeneration exposes the patient to serious haemorrhage. Administration of coagulation factors, such as in the form of fresh frozen plasma, should be preceded by antivenom to neutralise venom prothrombin activator as otherwise consumption coagulopathy may worsen.[11] Platelets may be required but whole blood is rarely needed.

Intravenous fluids, rhabdomyolysis and renal protection

After acute resuscitation, administer intravenous fluids in sufficient volume to maintain urine output at about 40 mL/kg per day in an adult and 1–2 mL/kg per hour in a child to prevent tubular necrosis as a consequence of rhabdomyolysis. Life-threatening hyperkalaemia and hypocalcaemia may develop with rhabdomyolysis. Haemofiltration or dialysis may be required.

Heparin

Although this anticoagulant has prevented the action of prothrombin activators in animal models of envenomation, it does not improve established consumption coagulopathy. It is not recommended. Emphasis instead should be on treating the cause by neutralising venom with antivenom.

Analgesia and sedation

Australian snake bite does not cause severe pain. However, sedation is required for the mechanically ventilated venom-paralysed victim and analgesia for rhabdomyolysis.

Care of the bite site

Usually no specific care is required. Occasionally the site may blister, bruise, ulcerate or necrose, particularly when a first-aid bandage has been in place for a considerable time or when the bite was by a member of the Black Snake genus, such as a Mulga Snake or Red-bellied Black Snake.

Other drugs

Antibiotics are not routinely required but should be considered as for any potentially contaminated wound. Sea-snake bites may cause Gram-negative infections. Tetanus prophylaxis should be reviewed.

SEA-SNAKE BITE

Some sea-snake venoms cause widespread damage to skeletal muscle with consequent myoglobinuria, neuromuscular paralysis or direct renal damage. Many have not been researched. The principles of treatment are essentially the same as for envenomation by terrestrial snakes. The venoms of significant species are neutralised with CSL Ltd Beaked Sea-Snake (*Enhydrina schistosa*) antivenom. If that preparation is not available, Tiger Snake or polyvalent antivenom should be used. Sea-snake bites are uncommon in Australia and no deaths have been recorded.

UNCOMMON AND EXOTIC SNAKE BITE

Zoo personnel, herpetologists and amateur collectors who catch, maintain or breed species of uncommon Australian snakes or who import or breed exotic (overseas) snakes are at risk, as are personnel in the Australian Quarantine and Inspection Service (AQIS) who encounter exotic species. Specific antivenoms to the venoms of uncommon Australian snakes do not exist, but neutralisation is provided by polyvalent antivenom or by monovalent antivenom, as indicated by the VDK.

Exotic snake antivenoms are maintained by Royal Melbourne Hospital (tel: +61 3 9342 7000), Royal Adelaide Hospital (tel: +61 8 8222 4000), Ballarat Hospital (tel: +61 3 5320 4316), Venom Supplies Ltd, Tanunda, South Australia (tel: +61 8 8563 0001), Australian Reptile Park (Tel: +61 2 4340 1022), Taronga Zoo (Mosman, tel: +61 2 9978 4757) and the Australian Venom Research Unit (AVRU) (tel: +61 3 8344 7753). The locations and stocks of antivenoms in Australia for treatment of bites by specific exotic snakes are maintained by AVRU at http://www.avru.org/reference/reference_avhold.html.

LONG-TERM EFFECTS OF SNAKE BITE

After appropriate treatment, recovery is expected but it may be slow, taking many weeks or months, particularly from a critical illness or after delayed presentation involving neurotoxicity and rhabdomyolysis. Isolated neurological or ophthalmic signs may persist. Long-term loss of taste or smell occurs occasionally.

SPIDERS

Although several thousand species of spiders exist in Australia, only Funnel-web Spiders (genera *Atrax* and *Hadronyche*) and the Red-back Spider (*Latrodectus hasselti*) have caused death or significant systemic illness. All spiders have venom and a few, particularly the White-tailed Spider (*Lampona cylindrata*) and the Common Black House Spider (*Badumna insignis*), have caused severe local injury, although this occurs rarely.[1,12,13] Causes for ulcerated skin lesions other than spider bites should be sought.

FUNNEL-WEB SPIDERS

Many species of the Funnel-web genera *Atrax* and *Hadronyche* inhabit Queensland, New South Wales, Victoria, Tasmania and South Australia, but only spiders from New South Wales and southern Queensland have caused significant illness and death. These are large dark-coloured aggressive spiders. A systematic review involving 138 cases identified 77 cases of severe envenomation with 13 deaths, but none occurred after introduction of antivenom in 1981 and the vast majority (97%) responded to antivenom therapy.[14] All deaths were attributed to the Sydney Funnel-web Spider (*A. robustus*)[1] which inhabits an area within an approximate 160 km radius of Sydney. It roams after rainfall, may enter houses and seeks shelter among clothes or bedding, giving a painful bite when disturbed.

Severe envenomation is also caused by the Southern Tree (*H. cerberea*), Northern Tree (*H. formidabilis*), Port Macquarie (*H.* sp. 14), Toowoomba or Darling Downs (*H. infensa*) and Blue Mountains (*H. versuta*) species. In contrast to other spiders, male Funnel-web Spiders have more potent venom than female spiders.

Bites do not always result in envenomation, but envenomation may be rapidly fatal. The early features of the envenomation syndrome include nausea, vomiting, profuse sweating, salivation and abdominal pain. Life-threatening features are usually heralded by the appearance of muscle fasciculation at the bite site, which quickly involves distant muscle groups. Hypertension, tachyarrhythmias, vasoconstriction, hypersalivation and bronchorrhoea occur. The victim may lapse into coma, develop central hypoventilation and have difficulty maintaining an airway free of secretions. Finally, respiratory failure, pulmonary oedema and severe hypotension culminate in death. The syndrome may develop within several hours but it may be more rapid. Several children have died within 90 minutes of envenomation, and one died within 15 minutes.[1] An active component in the venom is a polypeptide that stimulates the release of acetylcholine at

neuromuscular junctions and within the autonomic nervous system, and the release of catecholamines.

Treatment consists of the application of a pressure-immobilisation bandage, intravenous administration of antivenom and support of vital functions, which may include airway support, mechanical ventilation and intensive cardiovascular support.

RED-BACK SPIDER

This spider is distributed throughout Australia and is found outdoors in household gardens in suburban and rural areas. Related species and similar effects of envenomation ('latrodectism') occur in many parts of the world. Red-back Spider bite is the most common cause for antivenom administration in Australia, at 300–400 per annum. The adult female is identified easily. Its body is about 1 cm in size and has a distinct red or orange dorsal stripe over its abdomen. When disturbed, it gives a pinprick-like bite. The bite site becomes inflamed and, during the following minutes to several hours, severe pain exacerbated by movement commences locally and may extend up the limb or radiate elsewhere. The pain may be accompanied by profuse sweating, headache, nausea, vomiting, abdominal pain, fever, hypertension, paraesthesiae and rashes. In a small percentage of cases when treatment is delayed, progressive muscle paralysis may occur over many hours, requiring mechanical ventilation. If untreated, muscle weakness, spasm and arthralgia may persist for months after the bite.

If the effects of a bite are trivial and confined to the bite site, antivenom may be withheld; otherwise antivenom should be given intramuscularly or intravenously. The antivenom may be given intravenously in cases of refractory pain but the risk of anaphylaxis may be higher than by the intramuscular route, which is very low (<0.5%). A premedication with promethazine is recommended and epinephrine should be at hand. In contrast to a bite from a snake or Funnel-web Spider, a bite from a Red-back Spider is not immediately life-threatening. There is no proven effective first aid, but application of a cold pack or iced water may help relieve pain. Bites by *Steatoda* spp. (cupboard spiders) may cause a similar syndrome and can be treated effectively with Red-back Spider antivenom.[15]

BOX JELLYFISH

This creature, *Chironex fleckeri*, is probably the most venomous in the world. It has caused approximately 70 deaths in the waters off northern Australia. It has a cuboid bell up to 30 cm in diameter. Numerous tentacles arise from the corners of the bell and trail several metres. It is semitransparent and difficult to see by anyone wading or swimming in shallow water. The tentacles are lined with millions of nematocysts that, on contact with skin, discharge a threaded barb that pierces subcutaneous tissue, including small blood vessels. Contact with the tentacles causes severe pain and envenomation, from which death may occur within minutes. Death is probably due to both neurotoxic effects causing apnoea and direct cardiotoxicity, although the precise mode of action of the venom is unknown. In mechanically ventilated animals, fatal hypotension occurs rapidly on envenomation.[16] The skin that sustains the injury may heal with disfiguring scars.

First aid, which must be administered on the beach, consists of dousing the skin with acetic acid (vinegar), which inactivates undischarged nematocysts. Adherent tentacles can then be removed. Cardiopulmonary resuscitation may be required on the beach and continued en route to hospital where extracorporeal life support could be considered. An ovine antivenom is available but efficacy is doubtful in established critical illness. Prevention is of paramount importance: water must not be entered when this jellyfish is known to be close inshore. Wet suits, clothing and 'stinger suits' offer protection.

IRUKANDJI

Stings by the Irukandji, *Carukia barnesi* (Barnes' jellyfish), and by other Carybdeid jellyfish may cause a syndrome known as Irukandji syndrome.[17] *C. barnesi* is a small cubozoan jellyfish with a squarish bell a little more than 1 cm in diameter. Single tentacles trail from its four corners. When submerged it is virtually impossible to see.

Its sting is mild and marked only by a small area of erythema. However, severe general illness may follow with abdominal cramps, hypertension, back pain, nausea and vomiting, limb cramps, chest tightness and marked distress. Occasionally, cardiogenic pulmonary oedema has necessitated mechanical ventilation and inotropic therapy, while hypertension has caused two deaths by stroke. The mechanism is uncertain, but experimental studies in animals have shown that Irukandji extracts cause a hyperadrenergic syndrome secondary to massive release of catecholamines,[18] which may explain at least in part the cause of heart failure. Pain relief is the most important feature of management in mild to moderate cases. In a series of 10 victims with 'Irukandji syndrome', intravenous magnesium salts provided pain relief and a reduction in blood pressure,[19] but these observations are not supported by a randomised trial showing that magnesium salts did not influence the required amount of analgesia.[20] Antihypertensive therapy with phentolamine or a 'titratable' nitrate may be required in the initial phase of management.

AUSTRALIAN PARALYSIS TICK

This tick (*Ixodes holocyclus*) injects a toxin that causes flaccid paralysis after some 3–5 days of feeding on

humans. The onset of illness resembles that of Guillain–Barré syndrome. Prompt, careful and entire removal of tick(s) is necessary, followed by a period of observation to ensure that late-onset paralysis does not occur. No antitoxin is available.

BEES, WASPS AND ANTS

Anaphylactic reactions to bee and wasp stings cause approximately the same number of deaths in Australia each year as do snake bites, at an average of 2.3 per annum.[21] The common European Honey Bee (*Apis mellifera*) is largely responsible. Jumper and Bull Ants (*Myrmecia* spp.) may also cause anaphylaxis. Persons who develop reactions to bites should seek immunotherapy and always carry injectable epinephrine.

BLUE-RINGED OCTOPUSES

Several species of *Hapalochlaena* inhabit the Australian coastline. When handled, these octopuses bite and inject tetrodotoxin – a neurotoxin found in many different species of marine animals. It causes rapid onset of flaccid paralysis. Approximately a dozen deaths have been recorded. The required treatment is mechanical ventilation until spontaneous recovery occurs.

STINGING FISH

Numerous marine and fresh-water fish carry venom in glands attached to stinging spines. The most dangerous is the Stonefish (*Synanceia* spp.). When trodden upon, venom is injected. The immediate effect is extreme pain. Several deaths have been recorded, which are presumably due to the known depressive effects of the toxins on cardiovascular and neuromuscular function, and myotoxicity. An antivenom (CSL Ltd) is available. Local or regional nerve blockade may be required for pain relief. Other stinging fish, such as the fresh-water Bullrout (*Notesthes robusta*) also cause excruciating pain when their spines are contacted. Immersion of the affected limb in warm-to-hot water provides pain relief.

VENOMOUS CONE SHELLS

Many gastropod molluscs rapidly eject a venom-laden harpoon to almost instantaneously immobilise and kill prey. The numerous conotoxins, which are short proteins, stimulate or block neuronal and neuromuscular receptors, causing rapid death. A handful of human deaths have been recorded when shells have been carelessly or unwittingly handled. There is no antivenom. Mechanical ventilation would be required until spontaneous recovery occurs.

Ballistic injury

Michael C Reade and Peter D (Toby) Thomas

'Ballistics' is the study of projectiles. Strictly, this does not include the effect of blast, but as blast often wounds by accelerating projectiles, this chapter refers to both mechanisms of injury.

Patients with ballistic injury are uncommon in most parts of the developed world. However, understanding ballistic trauma is essential, as failing to do so can result in treatment (e.g. needless extensive debridement) worse than the injury itself. This chapter will hopefully remain a skimmed-over curiosity in an otherwise intensely studied book. For the minority who need to read it in detail, perhaps unexpectedly, we hope it can provide useful advice.

EPIDEMIOLOGY OF BALLISTIC TRAUMA

Military conflicts result in variable wound patterns, summarised in **Table 85.1**.[1–3]

The trend towards a higher proportion of head and neck wounds in recent conflicts (**Table 85.2**)[2–4] has been attributed to better protection from body armour.

CAUSES AND TIMING OF DEATH IN BALLISTIC INJURY

Seventy percent of deaths due to ballistic trauma occur due to brain injury or exsanguination within 5 minutes of wounding,[2] and almost none are survivable regardless of treatment. However, most ballistic wounds are not fatal. Of patients who died in the Vietnam War,[4] 25% had potentially correctable surgical causes, and 12% died of infections and other complications. While most preventable deaths occur in the first 1–2 'golden' hours after wounding, treatment in the 'platinum 10 minutes'[5] is frequently most important. Of preventable deaths, 60% are due to haemorrhage from extremities, 33% from tension pneumothorax, and 6% from airway obstruction.[6] Interventions to address these three mechanisms are central to the training of military personnel.[7]

RATIO OF KILLED TO WOUNDED

The ratio of killed to wounded depends on weapon systems employed, context, protective equipment and medical support. The mortality associated with different weapons systems in combat is shown in **Table 85.3**.[2,8]

The context of wounding is critically important. In modern war the wounded : killed ratio ranges from 1.9 : 1 to 13.0 : 1,[9] with an average over time of around 4 : 1.[2,4] Body armour and better medical care were advanced as possible explanations for the higher survival (ratio 10 : 1) of US casualties in Iraq,[10] although the higher proportion of blast casualties probably also contributed. Weapons used in a civilian context are more lethal, ranging from 0 : 1 to 1 : 3.14,[9] probably because civilian shootings occur at close range with unarmed victims who cannot escape. Higher than expected mortality in war suggests executions rather than combat deaths, and has been used as evidence of war crimes.[9]

BLAST TRAUMA

An explosion occurs when a substance rapidly undergoes a chemical or nuclear reaction, releasing energy in the form of a pressure wave, (usually) gas and heat. *High explosive* produces a supersonic pressure wave; slower burning (*conflagration*) produces a subsonic wave. The first force felt by an affected body is the static pressure wave, depicted in **Figure 85.1**. There is no mass movement of gas; rather pressure rapidly increases then becomes sub atmospheric. Hard surfaces reflect pressure waves, increasing the force in enclosed spaces.[11] The second force felt by a body in air is the mass movement of gases liberated by the exploding substance: the 'blast wind'.

MECHANISMS OF BLAST INJURY

The classification of blast injury is shown in **Table 85.4** and **Figure 85.2**.

PATHOPHYSIOLOGY OF PRIMARY BLAST INJURY

Primary blast injury is a common cause of death due to blast,[12] but (except in confined environments) is uncommon in survivors. For example, only 7% of US personnel wounded by blast surviving to hospital care had primary blast injury.[13] If the casualty is close enough to suffer a primary blast injury, secondary and tertiary effects are usually fatal. The immediate response to

Military rifle bullet	30–40%
Blast	22%
Blast fragmentation – randomly formed fragments	20% artillery shells; 10% grenades
Blast fragmentation – military preformed fragments	15% artillery shells; 5% grenades

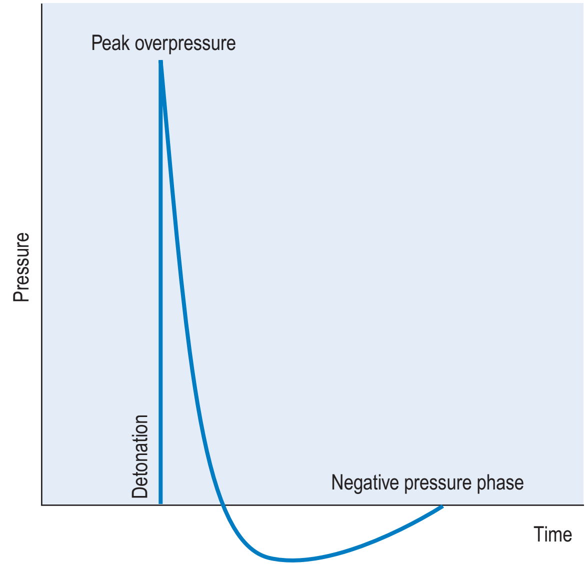

Figure 85.1 The blast static pressure wave in air.

blast to the chest is vagal-mediated hypotension, bradycardia and apnoea. Alternating overpressure and under pressure causes injury at the interfaces of tissues of different densities. This especially affects gas-containing organs (i.e. ears, lungs and gastrointestinal tract). The ear is the most sensitive. The eardrum can be ruptured (generally inferiorly in the pars tensa) by overpressures of approximately 35 kPa, and above 100 kPa rupture is nearly universal. There may be haemorrhage into the membrane without rupture. Rupture of the tympanic membrane may cause tinnitus, pain, hearing loss, and abnormal vestibular function. One-third of casualties experiencing rupture of the tympanic membrane will have permanent hearing loss.

The sensitivity of the tympanic membrane to blast led to recommendations to use this as an effective screen for blast injury to other organs. Unfortunately, this is not supported by clinical experience. Tympanic membrane disruption was present in only 50% of patients with other significant blast injury in one recent study.[13]

Blast lung injury, with shearing of the alveolar–capillary barrier, can cause air emboli, pneumothorax,

Table 85.4 Mechanisms of blast injury

TYPE OF BLAST INJURY	MECHANISM	EFFECTS
Primary	Static pressure wave, causing barotrauma due to overpressurisation and underpressurisation	Affects mainly air-filled organs: Tympanic membrane rupture 'Blast lung' Hollow viscera rupture (colon) Mild traumatic brain injury (mTBI) Eye injury (globe rupture, hyphaema, serous retinitis)
Secondary	Effects of projectiles propelled by the explosion	Penetrating injury Soft tissue trauma Traumatic amputation
Tertiary	Effects due to mass movement of air ('blast wind'), either directly or by interaction with the surroundings, including collapse of buildings	Blunt and penetrating injury Bone fracture Traumatic amputation Open or closed TBI Crush injury; entrapment
Quaternary	All other effects of blast, including burns, oxygen depletion, creation of dust	Surface and airway burns Inhalation of toxic gases (CO, cyanide) Exposure to radiation Asphyxiation

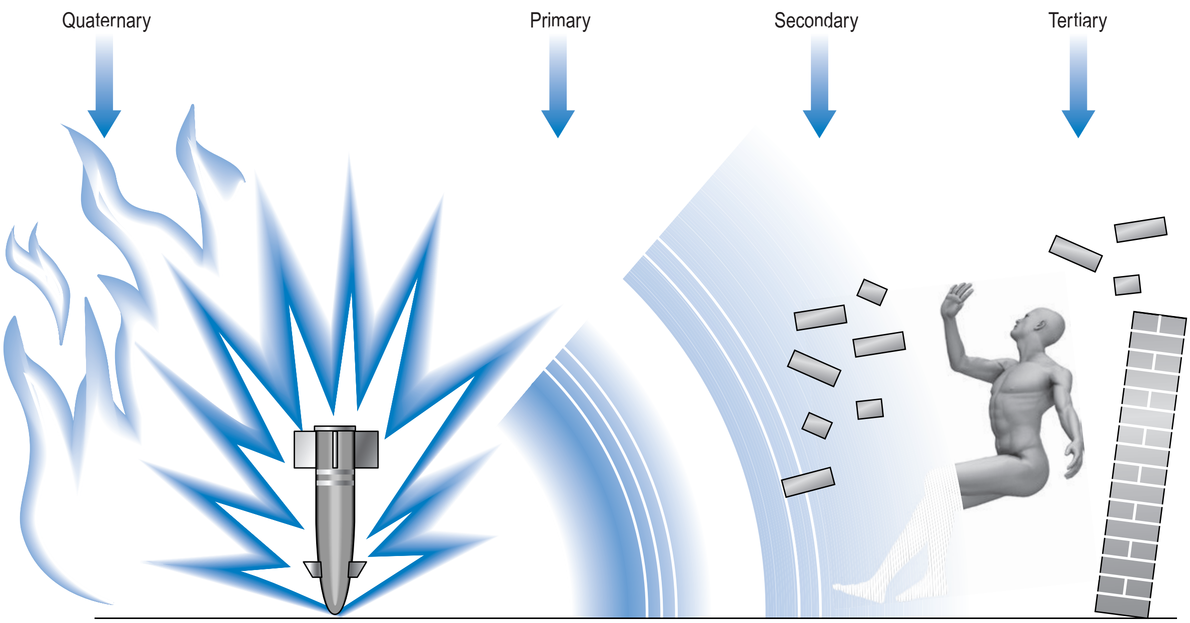

Figure 85.2 Mechanisms of blast injury. *(Courtesy of Major Anthony Chambers FRACS.)*

lung contusion, haemothorax, alveolar haemorrhage, mediastinal air, and subcutaneous emphysema.[14] As alveoli become flooded with fluid and cellular debris, the result is 'blast lung' (**Fig. 85.3**), with hypoxaemia secondary to ventilation–perfusion mismatch. The effect can appear similar to pulmonary contusion from blunt chest trauma. Arterial air emboli from alveolar–pulmonary venous communications cause most early deaths. Signs of air emboli include cerebral dysfunction such as altered affect, confusion, or focal neurological signs. When such findings are noted after an explosion, other closed head injuries must be excluded. Emboli to the coronary arteries may cause arrhythmias or ischaemia.

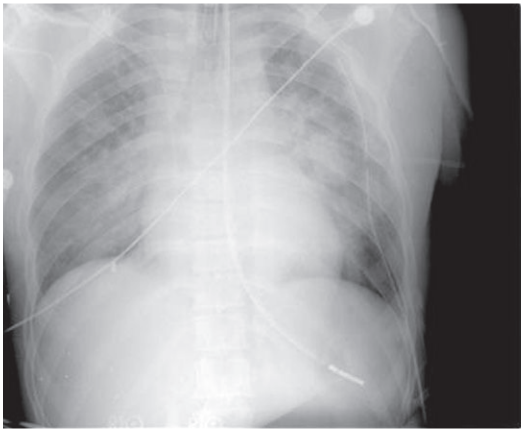

Figure 85.3 Blast lung, showing characteristic perihilar infiltrates. CT is a more sensitive modality than plain radiography. *(Courtesy of Australian Defence Force, Iraq, 2006.)*

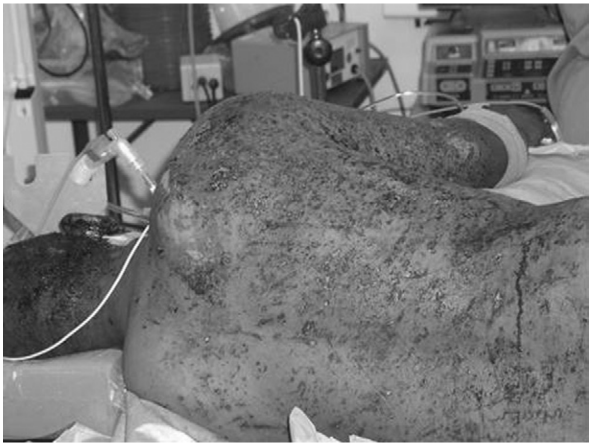

Figure 85.4 'Peppering' or 'battle acne' wounds characteristic of secondary blast injury. *(Courtesy of Australian Defence Force, Iraq, 2006.)*

Primary abdominal blast injury is uncommon, but occurs more frequently in enclosed spaces and under water. It frequently presents late with signs of peritonism and absent bowel sounds indicating visceral rupture. The colon is most commonly affected. Rarely, rupture of the liver or spleen may occur.

The role of primary blast injury in mild traumatic brain injury (mTBI) is unclear. mTBI can be associated with persistent and debilitating symptoms, many of which are shared with post-traumatic stress disorder (PTSD).[15] Diffusion tensor imaging MRI shows abnormalities in mTBI, but these appear to correlate poorly with clinical signs.[16]

PATHOPHYSIOLOGY OF SECONDARY AND TERTIARY BLAST INJURIES

Secondary blast injuries were more than three times more common than primary blast injuries during Operation Iraqi Freedom[17] and are the commonest cause of death, mainly from penetrating wounds to the head, neck or chest. Survivors of blast fragmentation injuries often have many low-velocity superficial wounds ('peppering' or 'battle acne': **Fig. 85.4**). Around 10% will have significant eye injuries,[18] particularly due to glass fragments in urban environments.

Traumatic limb amputation is only partly an effect of the blast wind. Primary blast injury fractures long bones, and the blast wind then detaches the distal portion. This is thought to explain why such amputations are typically not through joints.[19]

MANAGEMENT OF BLAST INJURY

Explosions often cause 'mass casualty' events. Depending on the circumstances, triage should be well away from the incident, as placement of further explosive devices is a common tactic targeting medical personnel.

EAR INJURIES

Tympanic membrane rupture is treated conservatively, as most heal spontaneously. About 25% will require delayed surgical closure.

BLAST LUNG

Blast lung typically develops over 24–48 hours and takes 7–10 days to resolve. Presentation ranges from a slight decrease in oxygen saturation to frothy sputum, profound hypoxaemia, and subcutaneous emphysema. A chest radiograph will distinguish pneumothorax, haemothorax, or pulmonary parenchymal failure from blast or other causes (e.g. inhalation of toxic gases). Recommendations for blast lung are mostly extrapolated from those for other causes of acute respiratory distress syndrome (ARDS), despite the known differences in pathogenic mechanisms. The risk of systematic air embolism increases with mechanical ventilation, suggesting minimising peak inspiratory pressures and permissive hypercapnia may be particularly useful. Excessive fluid administration should be avoided to minimise contusion. Pumpless arteriovenous extracorporeal oxygenation has been used successfully to transport profoundly hypoxaemic casualties from field hospitals to definitive care.

ABDOMINAL INJURIES

CT or focused assessment sonography for trauma (FAST) scanning will guide early management, but clinical suspicion in the days after the injury is even more useful given the likelihood of delayed presentation. Primary anastomosis for colorectal injuries associated with blast is thought unwise because of the high incidence of leak (30%), and most patients require colonic diversion.[20]

TRAUMATIC BRAIN INJURY

The most severe CNS blast effects are diffuse axonal injury, contusion and traumatic subdural haematoma,

all of which are managed according to conventional guidelines.[21] A patient with brief loss of consciousness after blast should have brain CT or MRI if there is persistent headache, vomiting, localising neurological signs or a Glasgow Coma Score less than 15.[22]

PENETRATING BALLISTIC TRAUMA

Penetrating ballistic trauma can be caused by fragments energised by explosive devices, or by projectiles from firearms.

BLAST FRAGMENTATION

Casing fragmentation multiplies many times the range and effect of smaller blast weapons such as grenades, mines and mortar bombs, producing fragments with predictable properties that optimise range, kinetic energy and probability of hitting a target. Larger blast weapons (bombs) rely on their greater energy to create effective fragments from surrounding rocks or debris.

BULLETS FROM FIREARMS

A *bullet* is a single projectile shot from a firearm. Modern bullets are attached to *cartridge cases* containing the *percussion cap* or *primer* and *propellant*; the entire structure forms a *round* of *ammunition*. Firearms firing bullets include *rifles* (with a long barrel that is 'rifled' with spiralling grooves inside that make the bullet rotate, increasing gyroscopic stability), *revolvers* (handguns with chambers that rotate to present each round to the barrel) and *pistols* (with short barrels but no rotating chambers). A *shotgun* with a smooth-bored barrel usually fires *shot* (round metal balls) rather than a single formed projectile.

PROJECTILE BALLISTICS

Rapidly expanding propellant gas accelerates the projectile through the firearm barrel. Projectile flight is determined by gravity, air friction and pressure resistance, wind, contact with solid objects (causing *ricochets*), and stability in flight. An aerodynamically shaped bullet tends to *yaw* to the side; this is opposed by gyroscopic stability, leading to a composite movement of *spin* (rotation around the long axis), *precession* (rotation of the rotational axis) and *nutation* (swaying of the rotational axis as it precesses). During flight, yaw progressively reduces. A bullet is therefore more likely to hit point-on after 100 metres of flight than after 3 metres (**Fig. 85.5**).[23,24]

WOUND BALLISTICS

Wound ballistics describes the interaction between a projectile and the biological tissue it hits. The amount of energy that is transferred is determined by the:

- *kinetic energy (KE) of the projectile:* KE = mass × velocity^2/2 × g. The kinetic energy *transferred* to the tissue is mass × (impact velocity − exit velocity)^2/2 × g

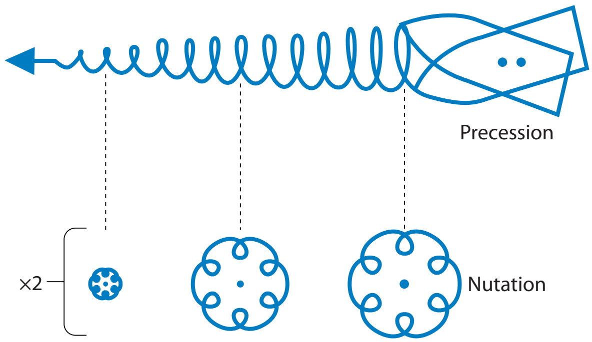

Figure 85.5 Precession and nutation. Both decrease as distance from the barrel increases. *(From Volgas DA, Stannard JP, Alonso JE. Ballistics: a primer for the surgeon. Injury 2005;36(3):373–9.)*

- *rotational energy of the projectile in flight:* usually negligible
- *shape and impact angle of the projectile:* an aerodynamically shaped bullet will impart more energy if it hits side-on; the degree to which this occurs is determined by its properties in flight, including the distance travelled and whether it has hit anything during flight
- *projectile deformability*
- *degree to which the projectile 'tumbles':* a rapid end-over-end motion does not occur; rather, if it remains intact, the bullet typically tumbles through 180 degrees and comes to lie base-first. Tumbling is the main reason why full metal jacket exit wounds are often larger than entry wounds
- *specific gravity of the tissue hit.*[25]

The terms 'high' and 'low' velocity are not as useful as 'power', incorporating projectile mass, and even less useful than the concept of energy transfer. Although most rifles are 'high-powered' and most pistols/revolvers 'low-powered', projectile energy is only one determinant of wound magnitude. A 'high-powered' rifle bullet may cause less trauma if it misses ribs and traverses a short path through the chest than a 'low-powered' pistol bullet that fragments after hitting a rib. Having said this, the kinetic energy of a rifle bullet is many times that from a pistol. Hitting bone, a pistol bullet frequently causes a simple fracture, whereas a rifle bullet causes fragmentation and extensive bone loss.[26] Most wounds caused by blast fragmentation (when the patient survives the explosion) are low-energy transfer.

Further determinants of the effect of the projectile are:

- the function of the tissue affected (e.g. the eye is damaged by minimal energy transfer)
- the ability of the affected tissue to tamponade haemorrhage (e.g. liver bleeds more than muscle).

BULLET DEFORMABILITY

Bullets are typically made of lead or lead–antimony, as high density preserves kinetic energy in flight. Pure lead bullets melt at velocities of greater than 2000 ft/s (≈600 m/s),[25] necessitating at least partial 'jacketing' in a more resilient substance (e.g. aluminium, brass, or steel). Military bullets (according to Third Hague Convention of 1899) must be completely encased in a 'full metal jacket' (a misnomer, as the base of the bullet may have no covering), which reduces deformation in tissues and so causes less 'unnecessary suffering'. By increasing the chance of non-lethal injury, an unintended consequence is to increase combat effect: a wounded enemy soldier consumes more resources than one who is dead. In contrast, hunting rifle bullets have a soft lead or polymer tip, increasing the chance of killing quickly and so reducing suffering. Bullets with hollowed-out points have greater air drag and shorter range, but deform so extensively that exiting the target is unlikely. This is beneficial for police wishing to reduce the chance of harming bystanders.

Doctors are sometimes asked by people concerned with compliance with the laws of armed conflict to classify the type of bullet found in a patient. *Any* bullet can deform and fragment, so finding no intact fully jacketed bullets does not allow this question to be answered (**Fig. 85.6**).[27]

MECHANISMS OF TISSUE DAMAGE

Bullets cause crushing/laceration, shock waves and cavitation. Crushing and laceration are caused by the direct force of the bullet, and are the principal mechanisms of injury due to 'low-powered' firearms. Serious injury generally results only if vital structures are damaged. Shock waves are caused when a 'high-powered' bullet compresses tissues. They cause little damage to most tissues[28] but can rupture gas-filled organs[25] and possibly cause neurological injury.[29] Cavitation results from the inertia imparted by a high-powered bullet to the tissues. As the tissues continue to move away from the bullet track, subatmospheric pressure sucks in debris. The *temporary cavitation* disrupts cells and their microcirculation, producing dead tissue around the wound track *up to* 30–40× the diameter of the bullet.[25] Cavitation is dependent on tissue elasticity; for example, liver is more affected than muscle. Inelastic gelatin blocks overemphasise the implications of temporary cavitation in many tissues.[30,31] The temporary cavity collapses to a much smaller permanent cavity, but the size of the permanent cavity is not an indicator of the extent of devitalised tissue.

MANAGEMENT OF PENETRATING BALLISTIC TRAUMA: BASIC PRINCIPLES

The International Committee of the Red Cross (ICRC) recommends as basic principles: early and thorough wound excision and irrigation, no unnecessary dressing changes, delayed primary closure, antibiotics as an adjuvant, antitetanus vaccine and immunoglobulin if necessary, no internal bone fixation, and early physiotherapy.[2]

Figure 85.6 Three fully jacketed bullets have entered the right thigh. Two have fragmented after contacting bone, while the third remains intact. *(Courtesy of Australian Defence Force, Afghanistan, 2009.)*

DAMAGE CONTROL SURGERY

Damage control surgery aims to stop haemorrhage, restore blood flow and control wound contamination.[32] Wounds are left packed if necessary, and temporarily closed. Restoration of bowel continuity, definitive debridement and wound closure are all deferred until physiology is optimised. This concept fits well with the ICRC basic principles and, as it requires general rather than specialist surgical expertise, can be performed in small hospitals close to the wounded.

DEFINITIVE MANAGEMENT

In general, re-inspection within 24–48 hours will be required for major wounds, with further debridement if required. This process continues every 48 hours until the wound can be closed. Even apparently clean wounds should not be closed before 4–5 days. Of 16 172 patients in the ICRC database, 41% required two operations, 14% three and 20% four or more.[2] Serial debridement in this manner is demanding; in mass casualties or resource-poor environments, the ICRC recognises this approach may be impossible and advises wider initial excisions.[2]

There are exceptions to the 'no primary closure' rule. The head, neck and genitals have such good blood supply that primary closure is possible in all but the

most contaminated wounds. Oral mucosa should always be closed primarily if possible. In penetrating brain injury the dura should also be closed, if necessary with a patch of pericranium or muscle aponeurosis.[2] Blood vessels that have been repaired should be covered by viable muscle if possible, with the skin left open.

MANAGEMENT OF SPECIFIC TYPES OF PENETRATING BALLISTIC WOUND

EXTREMITY WOUNDS: WOUNDS THAT DO NOT REQUIRE DEBRIDEMENT

Military[33] and civilian[2] consensus guidelines agree that not all bullet wounds require debridement. Extremities with entry and exit wounds <1 cm and no swelling or signs of injury to vital structures can have narrow skin margins excised and the channel irrigated. Wounds that do not penetrate deep fascia require only scrubbing, irrigation, dressings and antibiotics.

EXTREMITY WOUNDS: HOW MUCH TISSUE TO DEBRIDE?

Many published accounts[1,30,34] and the authors' own experience suggest that surgeons sometimes perform extensive debridement around high-powered bullet tracks in the belief that microvascular tissue damage is more extensive than can be seen. This approach, although once advocated in military texts,[35] ignores empirical studies[34] and the distinction between projectile energy and energy transfer.

In penetrating ballistic trauma, muscle viability was historically assessed using the 'four C's'[8] – *capillary* bleeding when cut, *contracts* when pinched, *colour* of red meat, and *consistency* firm. However, apparently dead muscle is often later found to be viable.[30,31,36] Along with substantial consensus,[8,28,30,37] we advocate initial debridement of only tissue and bone that is clearly ischaemic or not attached, with re-inspection and reassessment after 2–3 days. Drawing on experience in Afghanistan and Iraq, detailed consensus recommendations for extremity war wound debridement have recently been published.[33]

SUPERFICIAL BLAST FRAGMENTATION

There is debate about the optimal management of blast fragmentation penetrating trauma. Historically, military teaching was that all wounds should be surgically debrided, as most fragments carry bacteria. However, few open wounds develop infection,[38] implying at least some can be managed non-operatively. The foot wound in **Figure 85.7** was extensively contaminated and contained devitalised tissue, necessitating debridement. Conversely, the superficial wounds in Figure 85.4 were cleaned with a surgical scrub brush; no infection developed and the resultant scars were smaller than if each perforation had been explored. Published indications for surgical debridement of blast fragmentation wounds derived from case series are listed in **Table 85.5**.[39,40]

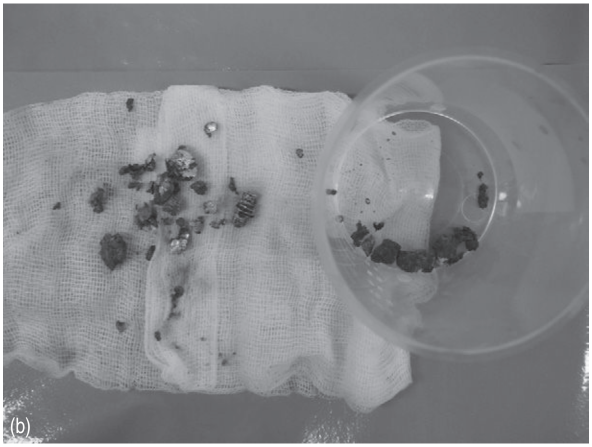

Figure 85.7 Extensive wound contamination and tissue loss due to blast fragmentation from a military explosive device. *(Courtesy of Australian Defence Force, Afghanistan, 2009.)*

BALLISTIC FRACTURE MANAGEMENT

Bone fragments without any soft tissue attachments should be removed.[26] However, *any* soft tissue attachment makes assessment of viability difficult, and at primary surgery such fragments should be retained. High-energy transfer fractures and fractures of the proximal tibia and fibula[41] often require deep fasciotomy to prevent compartment syndrome. Infection risk argues strongly for plaster, external fixation or traction rather than internal fixation of ballistic fractures.[26,42,43]

ABDOMINAL PENETRATING WOUNDS

Low-kinetic-energy bullets and blast fragmentation tend to produce discrete injury to abdominal organs. Up to 30% of civilian anterior abdominal and 67% of lower back gunshot wounds can be managed safely without surgery. This approach is increasing in US civilian practice,[44] probably associated with better and more widespread CT imaging; however, it fails in 21% of cases, and failure is associated with increased

Table 85.5 Indications for surgical debridement of blast fragmentation wounds

ORDOG ET AL 1993[39]	BOWYER 1997[40]
Presentation >24 h after wounding, without basic cleansing before presentation	Involvement of bone, pleura, peritoneum, or major vessels
Wound size >1–2 cm	Wound entry or exit >1–2 cm
Failure to comply with wound care instructions	Evidence of wound cavitation
Fractures	Obvious signs of infection Wounds due to buried mines

mortality.[44] High-energy transfer, haemodynamic instability, peritonitis, or lack of reassuring imaging all indicate laparotomy. In the military context, definitive surgery can avert a more prolonged admission for observation. Without comprehensive imaging, it is our practice and that of others[38] to explore all penetrating abdominal wounds (**Fig. 85.8**). If CT imaging is available, in the light of observational studies,[45] UK military guidelines allow for a selective non-operative approach in the minority of casualties with no peritonitis or haemodynamic instability who can be intensively monitored.[46]

THORAX

Penetrating thoracic injury is either rapidly fatal (e.g. 93% of patients with aortic injuries die before reaching hospital[47]), or managed with simple measures. Eighty-five percent of penetrating thoracic trauma patients who reach medical care can be successfully managed with intercostal catheter (ICC) drainage alone.[48] An ICC should always be placed through a new incision rather than the wound to prevent further haemorrhage. On placement of the ICC, Early Management of Severe Trauma[49] teaching is that >1500 mL initial haemorrhage or >200 mL/h ongoing loss for >2–4 hours necessitates operative thoracotomy. Emergency anterolateral thoracotomy should be considered in patients with penetrating thoracic injuries who arrive pulseless but with ECG activity within the last 6–10 minutes, with the intention of releasing cardiac tamponade, controlling haemorrhage (by cross-clamping the aorta or pulmonary hilum) and allowing internal cardiac massage to 'buy time' for aggressive fluid resuscitation. Thoracic penetrating injury below the level of the nipple, a positive FAST scan or abdominal signs suggests the projectile has traversed the diaphragm.

RETAINED FOREIGN BODIES

Easily accessible projectiles should be surgically removed. However, projectiles buried in healthy tissue *unequivocally do not need to be removed*, with some exceptions:

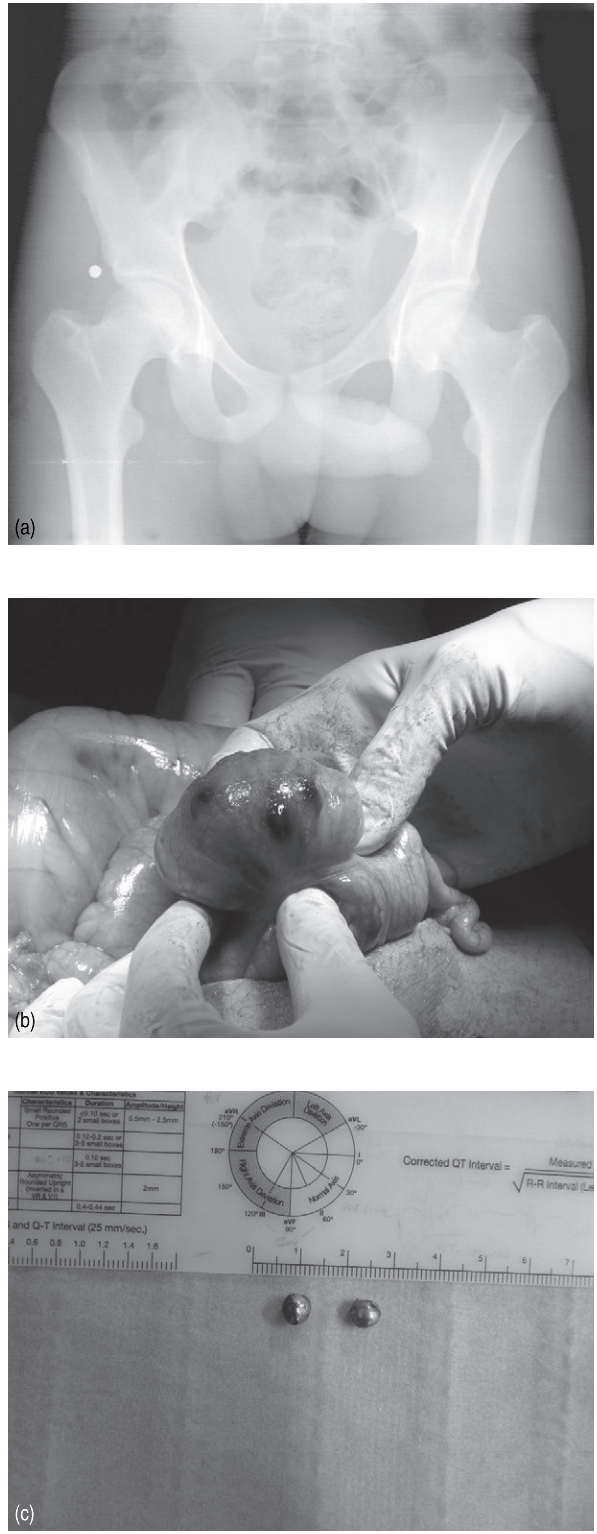

Figure 85.8 Localised bowel damage due to blast fragmentation. *(Courtesy of Australian Defence Force, Afghanistan, 2009.)*

- those lodged in joints or the subarachnoid space, in order to prevent lead arthropathy and systemic toxicity, joint destruction or neural damage
- those that appear to become the source of systemic infection
- those lying next to an internal organ (e.g. bronchus, heart), with the risk of subsequent erosion[31]
- those causing persistent pain, with the caveat that the psychological effects of a retained projectile are often profound, and this can influence pain perception.

Blood lead levels from projectiles retained in muscle peak at 1 month and in synovial fluid at 6 months.[50] If lead toxicity is the sole indication for projectile removal, the threshold serum levels are 10 µg/dL in children and 40 µg/dL in adults. Projectile removal should be attempted only after chelation with EDTA, dimercaprol, D-penicillamine or dimercaptosuccinic acid.[2]

HELPFUL INVESTIGATIONS

Pre- and intraoperative physical examination is the best single method of evaluating ballistic wounds.[34] However, projectiles often follow unpredictable paths. Radiology can be useful in triage, operative planning, and selection of cases for non-operative management. Experience in Iraq and Afghanistan led to a policy of all patients with substantial ballistic trauma having whole-body multidetector computed tomography (MDCT) scanning if this was available, unless operative intervention was immediately required to save life. Wound paths can be plotted using MDCT-derived data, allowing surgical planning.[51]

ICRC WOUND CLASSIFICATION

The ICRC wound classification system[2] categorises disease severity by measuring the size of the entry wound, exit wound and wound cavity, and involvement of fractures, vital structures and metallic foreign bodies. The result is a grade and type of wound. Unable to capture all aspects of anatomy and physiology and not accounting for multiple wounds, the ICRC system is not a predictor of outcome, but is nevertheless useful for quantifying the effects of weapon systems.

SPECIAL CASES OF BALLISTIC TRAUMA

LANDMINES AND IMPROVISED EXPLOSIVE DEVICES

Antipersonnel landmines wound by a combination of blast and fragmentation from their casing and from rocks and soil. Buried mines explode upwards through the leg, commonly resulting in traumatic amputation through the midfoot or distal tibia, with debris driven up fascial planes. Wound severity depends on the quantity of explosive, point of foot contact, debris near the mine, and footwear.[35] Bounding mines contain two charges: a small explosion propels a tethered casing upwards to 1–2 metres, which then explodes propelling fragments 50–100 metres. Horizontal spray mines also cause most of their effect by blast fragmentation. Air-dropped ‘butterfly’ mines rely on primary blast effect to maim when handled. Improvised explosive devices often mimic the effects of mines, but, being made from anything from artillery shells to household chemicals, their effects are more difficult to predict. All the principles articulated above apply to mine wounds, with particular emphasis on the need to remove soil. Topical negative-pressure dressings are perceived to be particularly useful,[52] but this approach is not yet supported by trial evidence.

INCENDIARY DEVICES (NAPALM, WHITE PHOSPHOROUS)

Military forces use white phosphorus and napalm as incendiaries, and white phosphorus is also used to create smokescreens. Both are also effective psychological weapons due to their capacity to inflict severe wounds. Napalm produces a burning gel that adheres to skin, invariably producing full-thickness burns involving muscle. A 10% burn typically causes rhabdomyolysis and renal failure.[2] Napalm commonly undergoes incomplete combustion, so carbon monoxide poisoning is common. White phosphorus fragments on explosion and ignites on air contact. Debridement requires keeping the wound moist. Dilute (1%) copper sulphate turns phosphorus black, which is safer and easier to remove. Alternatively, phosphorus particles glow in low light. Systemically absorbed white phosphorus causes hypocalcaemia and hyperphosphataemia, requiring intravenous calcium.[53]

BEHIND ARMOUR BLUNT TRAUMA (BABT)

Body armour, consisting of woven textiles with or without ceramic plate supplementation, effectively reduces the lethality of ballistic trauma.[54–56] However, larger rifle bullets can still kill by transmission of a force wave.[55] The immediate effects of BABT are vagally mediated apnoea and hypotension,[57] commonly accompanied by pulmonary and myocardial contusion, rib fractures, haemo- and pneumothorax. The commonest military bullet calibre, 5.56 mm, has negligible BABT potential, but larger calibres (eg. 7.62 mm and 50-cal.) carry substantial risk.[55]

INFECTION IN BALLISTIC INJURY

The two requirements for serious wound infection – a deep inoculum of bacteria and dead tissue, – are frequently present in ballistic trauma. This is particularly true of military wounds, with typically 3–6 different bacterial species isolated compared with only one in infected civilian wounds.[26] Bacteria are mainly

Box 85.1 Infectious Diseases Society of America and Surgical Infection Society guidelines for the prevention of infections associated with combat-related injuries[59]

I.v. antibiotic prophylaxis is indicated as soon as possible (ideally <3 h) after wounding.

Cefazolin 2 g i.v. every 6–8 hours (+metronidazole 500 mg i.v. q8–12 h for oesophageal, abdominal organ, CNS) is appropriate for all wounds except penetrating eye injury, for which levofloxacin 500 mg i.v./p.o. once daily is recommended.

Alternate agents depend on site of wounding:

- *extremity*: thoracic (excl. oesophageal); maxillofacial: clindamycin (300–450 mg p.o. t.i.d. or 600 mg i.v. q8 h)
- *oesophageal:* abdominal: single doses of ertapenem 1 g i.v. or moxifloxacin 400 mg i.v.
- *CNS:* ceftriaxone 2 g i.v. q24 h. Consider adding metronidazole 500 mg i.v. q8–12 h if gross contamination with organic debris. For penicillin-allergic patients, vancomycin 1 g i.v. q12 h plus ciprofloxacin 400 mg i.v. q8–12 h.

Duration of therapy in the absence of signs of infection: extremity; thoracic – 1–3 days; abdominal – 1 day after definitive washout; maxillofacial – 1 day; CNS: 5 days or until CSF leak is closed, whichever is longer.

Tetanus toxoid and immune globulin should be used as appropriate to immunisation status.

Enhanced Gram-negative coverage with aminoglycoside or fluoroquinolone is not recommended.

Addition of penicillin to prevent clostridial gangrene or streptococcal infection is not recommended.

Redose antimicrobials in the setting of large-volume blood produce resuscitation.

Use only topical antimicrobials for burns.

introduced into gunshot wounds by cavitation, but the bullet is not sterilised by firing and can also lead to infection.[25] Historically, the major causative organisms have been beta-haemolytic streptococci and clostridia. Although 'the best antibiotic is good surgery',[2] infection with both organisms is effectively prevented by prophylactic penicillin. Antibiotics alone may be sufficient for wounds left open with sufficient drainage.[58] US consensus guidelines for antimicrobial prophylaxis of combat-related wounds, drawing on experience of modern conflict, were recently published.[59] Essential points are summarised in **Box 85.1**.

Other organisations make different recommendations – for example, the ICRC recommends penicillin for all wounds except those involving hollow abdominal organs (requiring ampicillin+metronidazole +/− gentamicin) and thorax (requiring ampicillin), with the addition of metronidazole to maxillofacial or heavily contaminated soft tissue wounds and chloramphenicol for penetrating head trauma.[2]

Soil potentiates the ability of contamination to cause infection.[31] Wounds contaminated with soil should be thoroughly cleaned, potentially requiring more wound excision than otherwise. Infection is also particularly likely in haematomas,[31] which should be drained. If a wound requires debridement, earlier surgery is associated with less infection. For example, the 10% infection rate in wounds debrided in less than 6 hours after wounding rose to 25% in wounds debrided later.[60]

CONCLUSION

Medical planning and training in the management of ballistic trauma require balancing modern evidence-based medicine with the study of lessons acquired over centuries of conflict. Belligerents may be compelled to repeat the mistakes of the past; doctors should not.

Background information on 'biochemical terrorism'

Munita Grover and Michael Pelly

Biochemical terrorism is defined as the use of biological or chemical agents to intimidate, incapacitate, or eradicate crops, livestock, civilian and military personnel.[1] It is well suited for attack by poorer nations against the rich, and is known as a poor man's atom bomb, or asymmetric method of attack. The large-scale use of mustard and nerve gases in the Iran/Iraq war,[2] the dissemination of nerve gas sarin on the Tokyo underground,[3] and the discovery by UN inspectors in Iraq of SCUD missiles, rockets and aerial bombs primed with *Botulinum* and aflatoxins[4,5] have highlighted that the threat remains real (**Box 86.1**).

CHARACTERISTICS OF BIOLOGICAL WEAPONS

Intended target effects are either due to infection with disease-causing micro-organisms or other replicative entities, including viruses, fungi, and prions, or due to the toxins they elaborate. Their effects depend on the ability to multiply in the person, animal, or plant attacked.[6] Sequelae depend on host factors (state of nutrition, immunocompetence) and environment (sanitation, temperature, humidity, water quality, population density).[7]

CLASSIFICATION

Although classification of biological weapons can be taxonomy-based, for example, bacterial/viral/fungal, it is also useful to examine particular features such as:

- *infectivity:* proportion of persons exposed to a given dose who become infected.; reflects capability of agent to enter, survive and replicate
- *virulence:* ratio of the number of clinical cases to the number of infected hosts; this may differ for strains of the same pathogen
- *lethality:* ability of agent to cause death in an infected population
- *pathogenicity:* ratio of number of clinical cases to the number of exposed persons; reflects capability of agent to cause disease
- *incubation period:* time elapsing between exposure to the agent and first signs and symptoms of disease
- *contagiousness:* number of secondary cases following exposure to a primary case in relation to the total number exposed
- *stability:* ability of an agent to survive the environment.

Another useful classification system available is that from the CDC Atlanta:

CATEGORY A

High-priority agents include organisms that pose a risk to national security because they can be easily disseminated or transmitted from person to person, result in high mortality rates and have the potential for major public health impact, might cause public panic and social disruption, and require special action for public health preparedness. Examples include anthrax, botulism, plague, smallpox, tularaemia and viral haemorrrhagic fevers.

CATEGORY B

Agents of second highest priority include those that are moderately easy to disseminate, result in moderate morbidity rates and low mortality rates, and require specific enhancements of CDC's diagnostic capacity and enhanced disease surveillance. Examples include brucellosis, *Salmonella*, glanders, melioidosis, psittacosis, Q fever, ricin toxin, typhus, staphylococcal eneterotoxin B and viral encephalitis (**Box 86.2**).

ROUTES OF DISSEMINATION

- *Inhalational exposure using sprays or aerosols:* the optimal particle size for alveolar deposition is 0.6–5 μm. Those larger than this are filtered by the nose and smaller ones are exhaled. This can be achieved using aerosol generators mounted on stationary objects or primed onto trucks, cars, boats, cruise missiles and planes. Environmental factors such as wind velocity, cloud cover, rainfall and humidity affect the efficiency of dissemination[7]
- *Cutaneous:* via wounds and mucous membranes
- *Ingestion via food and water:* hand-to-mouth contact is a suitable vehicle (e.g. the Rajneeshee cult successfully disseminated *Salmonella* via salads, infecting 750 people in 1984)

Box 86.1 Potential weapons

Biological diseases	Chemical agents
Bacillus anthracis (anthrax)	*Blisters/vesicants*
Clostridium botulinum toxin (botulism)	Distilled mustard (HD)
Yersinia pestis (plague)	Lewisite (L)
Variola major (smallpox)	Mustard gas (H)
Francisella tularensis (tularaemia)	Nitrogen mustard (HN-2)
Viral haemorrhagic fever	Phosgene oxime (CX)
Coxiella burnetii (Q fever)	*Blood*
Brucella melitensis (brucellosis)	Arsine (SA)
Burkholderia mallei (glanders)	Cyanogen chloride (CK)
Ricin toxin (*Ricinus communis* – castor beans)	Hydrogen chloride
Staphylococcus enterotoxin B	Hydrogen cyanide (AC)
Nipah virus	*Choking/pulmonary damage*
Hantaviruses	Chlorine (CL)
	Nitrogen oxide (NO)
	Phosgene (CG)
	Nerve
	Sarin (GF)
	Soman (GD)
	Tabun (GA)
	VX
	Incapacitating
	LSD
	Cannabinoids

Box 86.2 Criteria for a successful biological weapon[6]

Assailant
Has methods to treat own forces and population

Target population
Non-immune
Little or no access to immunisation or treatment

Bioweapon
Consistently produces disease/death
Highly contagious or infective in low doses
Short and predictable incubation period
Difficult to identify in target population
Suitable for mass production, storage and weaponisation
Stable during dissemination
Low persistence after delivery

DETECTION OF A BIOTERRORIST EVENT

This may be obvious if large numbers of military personnel become ill with similar syndromes, but any release is likely to be a covert event. Furthermore, genetic engineering may result in altered pathogenicity, incubation periods, clinical effects and response to treatment or immunisation (**Box 86.3**).

Box 86.3 Epidemiological evidence of an attack

Increasing incidence of disease in a normally healthy population
Higher incidence in subgroups, e.g. outdoor workers/shared ventilation
Increasing numbers seeking help with similar symptoms
Rise in endemic disease at an uncharacteristic time
Large numbers of rapidly fatal cases
Any patient with an uncommon disease that has bioterrorist potential
Large numbers of dying animals or fish, and unusual swarms of insects

SPECIFIC BIOLOGICAL AGENTS

ANTHRAX

Anthrax[8] is an acute infectious zoonosis caused by *Bacillus anthracis*, a Gram-positive spore-forming bacillus. The infective dose is 8000–50 000 spores and routes of transmission include inhalation, ingestion and skin contact. Person-to-person transmission does not occur for the pulmonary form but secondary cutaneous lesions may occur after direct exposure to vesicle secretions. Spraying by aircraft is a potential threat to a large city; hence pulmonary exposure is the most likely route in a mass casualty situation.

CLINICAL FEATURES

Pulmonary exposure[9,10]

The incubation period is 2–60 days. The prodrome has flu-like symptoms. There may be interim improvement followed by respiratory failure and cardiovascular collapse. A widened mediastinum is seen on CXR, owing to haemorrhagic mediastinitis and lymphadenopathy. Gram-positive bacilli are found on blood cultures.

Cutaneous exposure

The incubation period is 1–7 days. Mostly the head, hands and forearms are affected, with pruritis, erythema, oedema and maculopapular lesions progressing to depressed black eschars within 2–6 days. Eschars fall off without scarring.

Gastrointestinal exposure

The incubation period is 1–7 days, usually following ingestion of infected meat. It presents with abdominal pain, cramps, haematemesis and bloody diarrhoea followed by toxaemia and cardiovascular collapse. There are Gram-positive blood cultures.

Post-exposure management[11]

There should be universal precautions for medical personnel, including warning the laboratory and coroner's personnel regarding pathology specimens. Contact the infection control team.

Handle fomites minimally. Thoroughly decontaminate with soap and water, and disinfect surfaces with 0.5% hypochlorite solution.

TREATMENT

Most strains used for bioterrorism will produce beta lactamases, and cephalosporinases were produced by

the latest cases in the USA. Appropriate antibiotics include:

- *ciprofloxacin:* adults 500 mg b.d. for 8 weeks; children 20–30 mg/kg per day
- *doxycycline:* adults 100 mg b.d. for 8 weeks; children 5 mg/kg per day
- *amoxicillin:* in children and pregnant patients 40 mg/kg per day (max 500 mg t.d.s.) is appropriate if the organism is penicillin-sensitive.

Immunisation with anthrax vaccine consists of 3 doses at 0, 2 and 4 weeks. Prophylaxis of contacts should continue for 8 weeks and include immunisation if exposure is confirmed. Preventative immunisation using an inactivated cell-free vaccine is available but presently only administered to military personnel.

BOTULISM

Botulism[5] is caused by *Clostridium botulinum*, an anaerobic Gram-positive bacillus that produces a neurotoxin. Seven forms of the toxin have been identified from A to G, but human botulism is due mainly to strains A, B, or E. The neurotoxin contains a zinc protease that acts at the presynaptic terminal of the neuromuscular junction to prevent the fusion of vesicles of acetylcholine with the presynaptic membrane, therefore preventing release of acetylcholine leading to a flaccid paralysis. The LD_{50} for type A is 0.001 μg/kg. Routes of exposure are either inhalation or ingestion, and there is an incubation period of 12–36 hours. Person-to-person transmission does not occur.

CLINICAL FEATURES

Clinical features include a responsive patient with no fever. There is a symmetric descending flaccid paralysis in a proximal-to-distal pattern without a sensory deficit. Cranial neuropathies (mainly bulbar) lead to diplopia, dysphagia, dysphonia and dysarthria. Respiratory dysfunction may occur owing to upper airway obstruction or muscle paralysis. The diagnosis is clinical, and confirmation is with the mouse bioassay in which mice are pretreated with antitoxin and exposed to the patient's serum. A pentavalent toxoid vaccine is available for prevention, but routine immunisation is not recommended.

TREATMENT

Patients should be monitored with frequent assessment of gag, cough reflexes, inspiratory force and vital capacity. Mechanical ventilation may be protracted, and may be punctuated by nosocomial infections requiring antibiotics.

Aminoglycosides and clindamycin are contraindicated because of their ability to increase blockade.[12] Administration of the trivalent (A, B, E) antitoxin should not be delayed while awaiting confirmation of the diagnosis. This horse serum has <9% hypersensitivity reactions and <2% incidence of anaphylaxis. Skin testing is advisable.[13] A heptavalent antitoxin is under investigation. Passive administration of neutralising antibody minimises further damage.[14]

Treatment of children, pregnant women and immunocompromised patients should be no different; all have received equine antitoxin without short-term sequelae. Prophylaxis of contacts involves close observation and, at the first sign of illness, treatment with antitoxin, neutralising antibody and administration of the pentavalent toxoid vaccine.

SMALLPOX

Smallpox[15] is an acute viral illness caused by variola virus (orthopoxvirus). The last documented case was in Somalia in 1977. It is transmitted from person to person via the airborne route, and its release into a non-immune population would be catastrophic.[16] The infective dose is 10–100 virions, with an incubation period of 7–17 days. In a non-immune society, the impact would be devastating as the human–human spread would be difficult to check, and many countries have very poor health structures with overcrowding in the cities. Also, the impact of global travel would change the epidemic and allow it to move rapidly from continent to continent. There are two other major factors that may change the profile of a predicted epidemic: the potential use of new antiviral agents against smallpox and the HIV epidemic. Predictions are difficult.

CLINICAL FEATURES[17]

There is a flu-like prodrome with malaise, fever, and headache. There is also a synchronously evolving maculopapular rash forming pustules over the head and extremities, and the mouth and pharynx may also be affected. Multi-organ failure commonly complicates smallpox. Diagnosis is clinical with confirmation by identification of brick-shaped virions from vesicular fluid using electron microscopy.

PREVENTION

Routine vaccination with vaccinia virus stopped in 1972. The immune status of vaccinated individuals is unclear, but if a single-dose vaccine was administered it is assumed the subject is non-immune. A preventative vaccination programme is currently under review.

TREATMENT

Vaccinate within 4 days of exposure.[18] However, complications include: post-vaccinial encephalitis, vaccinia gangrenosa, eczema vaccinatum, generalised vaccinia and inadvertant inoculation. Five groups are considered high risk for these. They are: pregnancy, HIV infection, chemotherapy, eczema and immune disorders.[19] In these cases, vaccinia immune globulin should be given simultaneously. Other treatments include:

- supportive care with isolation
- antibiotics for secondary bacterial infections

- cidofovir, a nucleoside DNA polymerase inhibitor, which is under investigation but needs to be given i.v. and causes renal toxicity.[20]

PLAGUE

Plague[21] is an acute bacterial disease caused by the Gram-negative *Yersinia pestis*, from the *Enterobacter* species.[22] Although usually transmitted by fleas causing bubonic and septicaemic plague, a bioterrorist event is likely to be airborne resulting in pneumonic plague. The infective dose is <100 organisms, and has an incubation period of 2–3 days. It is unlikely that spread would be person to person.

CLINICAL FEATURES

Plague presents with fever, haemoptysis, chest pain and dyspnoea. Gram-negative rods are found in mucopurulent sputum, and on Wright's, Giemsa or Wayson stain appear as bipolar rods with a safety-pin appearance. The diagnosis can be confirmed on blood culture and with fluorescent antibody testing. There is radiographic evidence of bronchopneumonia, and multi-organ failure soon develops. Until 72 hours of antibiotic therapy have been completed, plague is communicable.

PREVENTION

A formalin-killed vaccine exists but is ineffective and unavailable. Post-exposure immunisation has no benefit.

TREATMENT[21]

Once the diagnosis is considered, isolation and universal precautions should be instituted. Historically streptomycin (1 g b.d. i.m.) reduced mortality to 5%, and gentamicin (5 mg/kg per day) has also been used successfully. Tetracycline and doxycycline (100 mg b.d.), have been used, but in Madagascar 13% of strains are resistant to doxycycline. Animal studies have demonstrated efficacy of fluoroquinolones including ciprofloxacin (400 mg b.d.), ofloxacin and levofloxacin. No human trials exist so far. Chloramphenicol (25 mg/kg q.i.d.) is recommended for plague meningitis.

CHARACTERISTICS OF CHEMICAL AGENTS

The North Atlantic Treaty Organization definition of a chemical agent is a 'chemical substance which is intended for use in military operations to kill, seriously injure, or incapacitate people because of its physiological effects'.[2] In addition to physiological effects these agents promote psychological warfare.[23]

POSSIBLE ROUTES OF DISSEMINATION

The principal hazard is inhalation of liquid, vapour, or droplets (0.6–5 μm). Delivery may be by artillery shells, missiles or aerial bombing. In the Tokyo subway attack in 1995, terrorists left plastic bags on the subway filled with Sarin after piercing them with umbrella tips. There were 3796 casualties and 12 deaths.[3]

Toxicity depends on the concentration and time of exposure, and is measured in units of concentration and time (mg/min m^3), known as the Haber product.[7] Most chemical agents are designed to penetrate the skin, respiratory epithelium and cornea, unlike biological agents. Penetration is promoted by thinner, more vascular, moister, hairy skin, and by high humidity, spills and aerosols.

RICIN

Ricin is one of the most toxic biological agents known – a Category B bioterrorism agent and a Schedule number 1 chemical warfare agent. Ricin toxin can be extracted from castor beans, purified and treated to form a pellet, a white powder, or dissolved in water or weak acid to be released as a liquid. It is stable under ambient conditions. Particles of <5 μm have been used for aerosol dispersion in animal studies. Ricin particles can remain suspended in undisturbed air for several hours and finally resuspension of settled ricin from disturbed surfaces also may occur.

TRANSMISSION

Ricin is transmitted through skin contact, or by the airborne route through release of ricin in the form of a powder, or a mist, or reaerosolisation of ricin into the air from disturbed surfaces. Ricin would need to be dispersed in particles smaller than 5 μm to be used as an effective weapon by the airborne route. It is very difficult to prepare particles of this size. Routes of exposure include inhalation, parenteral (injection), ingestion, dermal contact (exposure risk is low; absorption through non-intact skin or via a solvent carrier), or ocular contact. Although ricin may adhere to skin, person-to-person transmission through casual contact has not been reported. Despite the fact that ricin may adhere to clothing or be present on surfaces, there is low potential for transmission via contact with contaminated clothing or contaminated surfaces.

RISK GROUPS

There is worldwide distribution of castor plants. Ricin is produced when castor oil is made from castor beans, but the general public is not considered at risk for exposure. Those at particular risk include: (i) persons in or around castor-oil-processing plants (however, it would take a deliberate act to make ricin and use it as a poison); (ii) persons in the dispersal area of a ricin aerosol release if ricin is used as an agent of terrorism; (iii) persons who are victims of parenteral injection with ricin; (iv) persons who ingest castor beans, or food or water contaminated with ricin. It is not known whether certain populations are more vulnerable to the health

effects of ricin exposure (e.g. children, pregnant women, the elderly, those with immunosuppression, or underlying respiratory or gastrointestinal tract disease); however, persons with pre-existing tissue irritation or damage who are exposed to ricin may sustain further injury and greater absorption of ricin toxin.

PATHOGENESIS

Ricin is a toxalbumin, a biological toxin whose mechanism of action is inhibition of protein synthesis in eukaryotic cells; cell death results from the absence of proteins. The effects of ricin poisoning depend upon the amount of ricin exposure, the route of exposure and the person's premorbid condition. Ingestion and mastication of three to six castor beans is the estimated fatal dose in adults. The fatal dose in children is not known, but is probably less. Most cases of castor bean ingestion do not result in poisoning, because it is difficult for ricin to be released from ingested castor beans, ricin release requires mastication, and the degree of mastication is likely to be important in determining the extent of poisoning. Ricin is not as well absorbed through the gastrointestinal tract compared with injection or inhalation. Inhalation or injection of ricin would be expected to lead to a more rapid onset of symptoms of ricin poisoning and to a more rapid progression of poisoning compared to ingestion, given the same exposure amount.

Data on inhalational exposure to ricin in humans are extremely limited, and systemic toxicity has not been described. Animal studies suggest that inhalation is one of the most lethal forms of ricin poisoning. Following severe ricin poisoning, damage to vital organs may be permanent or have lasting effects. No long-term effects are known to exist from ricin exposure that did not result in symptoms.

LABORATORY DIAGNOSIS AND TESTS

Non-specific laboratory findings in ricin poisoning include:

- metabolic acidosis
- increased liver function tests
- increased renal function tests
- haematuria
- leucocytosis (two- to five-fold higher than normal value).

There are no specific clinically validated assays for detection of ricin that can be performed by the hospital/health care facility clinical laboratory. Tests for ricinine, an alkaloidal component of the castor bean plant, are being developed. The potential uses of tests for either ricin or ricinine in human biological samples would primarily be for purposes of confirming exposure or assessing the prevalence of exposure rather than diagnostic use as the results would most likely not be immediately available. Laboratory criterion for diagnosis include detection of ricin in environmental samples. Laboratory tests performed on ricin-suspicious samples include:

- time-resolved fluorescence immunoassay: antibody binds to ricin
- polymerase chain reaction for the ricin protein.

TREATMENT

Because no antidote exists for ricin, the most important factor is avoiding ricin exposure in the first place. If exposure cannot be avoided, then rapid elimination and supportive care targeted at the route of exposure are required. This might include respiratory support, intravenous fluids and management of shock, prevention of seizures, enteral charcoal and ophthalmic irrigation.

SARIN

Sarin ($C_4H_{10}FO_2P$, isopropylmethylphosphofluoridate) is a colourless, odourless liquid at room temperature. It is volatile and incompatible with metals or concrete, which lead to production of hydrogen gas. Hydrolysis of Sarin forms acid. It is thermally stable <49°C, but clings to clothing and releases slowly for 30 minutes. Toxicity is through inhibition of the enzyme acetylcholinesterase (**Table 86.1**).

The route of exposure determines which clinical features appear first.[24] Post inhalation respiratory and eye symptoms appear, whereas post cutaneous exposure diaphoresis and muscle fasciculation occur. Immediate first aid is to remove the patient from the area of danger to a well-ventilated area before removal of clothing, and decontamination of the skin. This can be achieved using mists of water, or dilute sodium hypochlorite. Eyes are irrigated with water or normal saline.

Assessment follows airway, breathing and circulation principles. Patients with compromised airways due either to direct effects or secondary to reduced level of consciousness require intubation and positive-pressure ventilation. Aggressive suctioning may be needed for the bronchial secretions.

TREATMENT

- *Anticholinergics:* to antagonise the muscarinic effects, usually i.v. atropine in 2 mg doses, every 3–5 min until the patient is atropinised; atropine may need to be continued for 24 h at 2 mg/h[2]

Table 86.1 Sarin toxicity

MILD	Rhinitis, dyspnoea, miosis, blurred vision
MODERATE	Diaphoresis, drooling, bronchospasm, nausea, vomiting, cramps, weakness, twitching, headache, confusion
SEVERE	Involuntary defaecation/urination, convulsions, respiratory arrest, coma, death

Table 86.2 Features of mustard gas toxicity

EYES	Lacrimation, conjunctivitis, photophobia
SKIN	Erythema, blistering, partial- to full-thickness burns
RESPIRATORY TRACT	Rhinorrhoea, tracheobronchitis, bronchopneumonia
SYSTEMIC	Nausea, vomiting, diarrhoea, bradycardia, hypotension

- *Oximes:* to reactivate the anticholinesterase enzyme at nicotinic sites (e.g. pralidoxime mesilate 30 mg/kg by slow i.v. injection, up to 2–4 g); this should be prompt, as dealkylation of the inhibited enzyme renders it resistant to reactivation
- *Prophylactic anticonvulsants:* to prevent seizures, diazepam 5 mg by any route has been shown to reduce morbidity in animal studies.

MUSTARD GAS

Mustard gas ($C_4H_8Cl_2S$, bis-(2-chloroethyl) sulphide) is a yellow oily liquid at room temperature. It has a faint garlic odour and evaporates to form a vapour that penetrates clothing. There is a low mortality, but it tends to incapacitate. It is a bi-functional alkylating agent that is carcinogenic (oral cavity, larynx, bronchus), and irritates skin and mucosa. Mustard gas is also myelotoxic (pancytopenia) and teratogenic. Assessment is similar to that of Sarin (**Table 86.2**).[25]

TREATMENT

Patients with large burns are resuscitated as any other burn injuries; however, fluid losses are transudates so protein losses are less.[26] Pain control is important and frequently requires analgesics, such as morphine. Tense blisters are dressed with silver sulfadiazine. Mustard burns take at least 12 weeks to heal, but early excision and grafting do not reduce healing time.[27,28] Eye lesions usually heal in 2 weeks, and are aided by topical antibiotics and saline irrigation. Oxygen, antibiotics for secondary pneumonia, physiotherapy and ventilation are the mainstays of treatment for respiratory effects.

ACUTE RADIATION SYNDROME

Acute radiation syndrome (ARS) can also be termed radiation poisoning, radiation sickness or radiation toxicity. It is a collection of symptoms and signs that present within 24 hours of exposure to high amounts of ionising radiation. It can last for months but acute radiation syndrome really refers to the acute medical problems rather than ones that develop after a prolonged period of time. There is a dose–response relationship to both the onset and type of symptoms, with smaller doses resulting in gastrointestinal effects such as nausea and vomiting, and symptoms related to fall in blood count such as infection and bleeding, whereas relatively larger doses tend to produce neurological effects and rapid death. Treatment is largely supportive with blood transfusions and antibiotics.

TYPES OF RADIATION

Alpha and beta radiation have low penetrating power and are unlikely to affect internal organs from outside the body. Any type of ionising radiation can cause burns but alpha and beta radiation do so only if fallout actually causes contamination of individuals' clothing. Gamma and neutron radiation can travel much further distances and penetrate the body easily, so whole-body irradiation generally causes ARS before skin effects are evident. Local gamma irradiation can cause skin effects without any sickness.

PATHOPHYSIOLOGY

One of the predictors of the radiation symptoms is whole-body absorbed dose of radiation. Other equivalent measurements include effective dose and committed dose, which are used to gauge long-term biological effects such as cancer incidence, but they are not designed to evaluate ARS. Absorbed dose is measured in units of gray (Gy) or rad.

Diagnosis is made on history of significant exposure to radiation and absolute lymphocyte count can give a rough estimate of radiation exposure. Time from exposure to vomiting can also give estimates of exposure levels if they are less than 1000 rad.

SIGNS AND SYMPTOMS

The three main systems affected tend to be haematopoietic, gastrointestinal and neurological. These symptoms can be preceded by a prodrome and the speed of onset of symptoms related to the radiation exposure, with greater doses resulting in a shorter delay in symptom onset.

Any prodrome tends to have symptoms and signs common to other illnesses and by itself do not indicate ARS. Nausea, vomiting, headaches and fever with a short period of skin reddening can occur, but these resolve very quickly and therefore the diagnosis of ARS can be overlooked.

SKIN

Cutaneous radiation syndrome refers to the constellation of skin effects after exposure. It usually happens within a few hours after irradiation, consisting of redness, associated itching, followed by a latent period

that can last from a day to weeks, during which there is intense reddening, blistering and ulceration of the irradiated site. Very large doses can cause permanent hair loss, damaged sebaceous and sweat glands, atrophy, fibrosis and increased skin pigmentation together with ulceration or necrosis of the exposed tissue, such as seen at Chernobyl and during the Litvinenko exposure in 2006.

HAEMATOPOIETIC

Aplastic anaemia leads to increased risk of infections due to leucopenia, bleeding tendencies due to thrombocytopenia and anaemia due to reduced red cell counts.

GASTROINTESTINAL

The main symptoms encountered include nausea, vomiting, loss of appetite, and abdominal pain. Vomiting is a marker for high exposure doses and therefore heralds a likely fatality. Death is common without bone marrow transplantation.

NEUROVASCULAR

This syndrome occurs at doses greater than 30 Gy, but can occur below 10 Gy. It presents with symptoms of dizziness, headache and decreased levels of consciousness occurring within minutes to a few hours, and with an absence of vomiting. It is invariably fatal.

PREVENTION

1. *Exposure:* increasing the distance from the radiation source reduces the dose according to the inverse-square law for a point source. Distance can sometimes be effectively increased by means of a simple handling source.
2. *Time:* minimise exposure duration.
3. *Shielding:* matter will attenuate radiation, so placing any mass, dirt, sandbags, vehicles between humans and the source will reduce the radiation dose. A gas mask, dust mask, or good hygiene practices may offer protection, depending on the nature of the contaminant. Potassium iodide tablets can reduce the risk of cancer in some situations.
4. *Fractionation of dose:* if a dose is broken up into a number of smaller doses then the total dose causes less cell deaths.

MANAGEMENT

Treatment is supportive with the use of antibiotics for infection in neutropenic patients, blood products to support the haematopoietic system, colony-stimulating factors to boost bone marrow production and eventually cell stem transplant as clinically indicated. Symptomatic measures in order to decrease nausea and vomiting and dressings for skin lesions may further help management.

Pharmacokinetics, pharmacodynamics and drug monitoring in critical illness

Christine Chung

Pharmacokinetics (PK) describes a drug's journey through the body and is quantified by the measurement of plasma levels. The four parameters usually studied are absorption, distribution, metabolism and excretion. Pharmacodynamics (PD) examines the effects of the drug on the body during its time course. The relationship between the two can be used to individualise dosing regimens by predicting how a drug will behave in a given patient.

Most PK–PD studies are performed in patients outside of the intensive care setting, so the results are not always applicable to this patient group. Data from ICU studies may be more accurate at predicting outcome but, due to labile PK–PD of the critically ill, optimisation of treatment still remains a therapeutic challenge. As a patient improves or deteriorates clinically, dosing may need adjustment depending on the drug in question.

The aim of this chapter is to provide the reader with the basic principles of pharmacokinetics and pharmacodynamics and to aid in the understanding of drug dosing in the ICU patient.

PHARMACOKINETICS

The basic terms used in pharmacokinetics include bioavailability (F), target (desired) plasma concentration (C_p), volume of distribution (V_d), clearance (Cl) and half-life ($t_{1/2}$).

Bioavailability is the fraction of administered dose that reaches the systemic circulation[1] and is dependent on many variables including absorption (see below). The value of F for the intravenous (i.v.) route is usually 1 unless the drug in question is a prodrug (i.e. requires metabolism to its active form). For an oral dosage form, F would also be less than 1 in the majority of cases as a certain percentage of the drug can be lost at each stage of the journey from the gastrointestinal tract to its site of metabolism. For example, bioavailability of digoxin tablets is 0.63 and the liquid 0.75.[2] Therefore, strictly speaking, converting from an oral to an i.v. dose requires a 20–30% reduction to provide an equivalent amount of drug. In practice, it is recommended that the dose is reduced by 25%. C_p is the desired plasma concentration.[1]

ABSORPTION

In order for a drug molecule to be absorbed, it is required to cross a membrane. Membranes are comprised of a phospholipid bilayer, with a hydrophilic exterior and a hydrophobic core. Fat-soluble drugs use passive diffusion to cross the membrane barrier. Extremely small water-soluble molecules gain entry through narrow aqueous membrane channels. The majority of water-soluble drugs travel by other mechanisms (e.g. via an active transport process facilitated by an energy source, i.e. ATP).[3]

Unionised molecules pass freely through membranes; ionised molecules do not.

Therefore, lipid-soluble drugs such as phenytoin can be easily absorbed from the gastrointestinal tract whereas large, water-soluble and polar drugs such as gentamicin cannot (**Fig. 87.1**).

Oral

The majority of drugs used in critical care are administered via the intravenous route. There are occasions, however, where an essential drug exists only in the oral form. How much is absorbed via the enteral route is governed by many factors such as:

- whether the pH of the stomach is optimal (e.g. bioavailability of atazanavir is significantly reduced by agents used for stress ulcer prophylaxis. Proton pump inhibitors reduce atazanavir's solubility by raising the pH of the stomach.[4] Weak basic drugs such as atazanavir require a low pH for absorption.)
- presence of enteral feed that may significantly reduce the efficacy of certain drugs (e.g. phenytoin is best administered in the middle of a 4-hour rest period from enteral feed[5])
- presence of other drugs that may bind and reduce bioavailability if administered at the same time, e.g. ciprofloxacin and ferrous fumarate[6]
- formulation of drug administered (e.g. liquid versus tablet)
- gut transit time (e.g. profuse diarrhoea may lead to reduced time for absorption and potentially therapeutic failure)
- gut integrity and perfusion (often reduced in the critically ill)

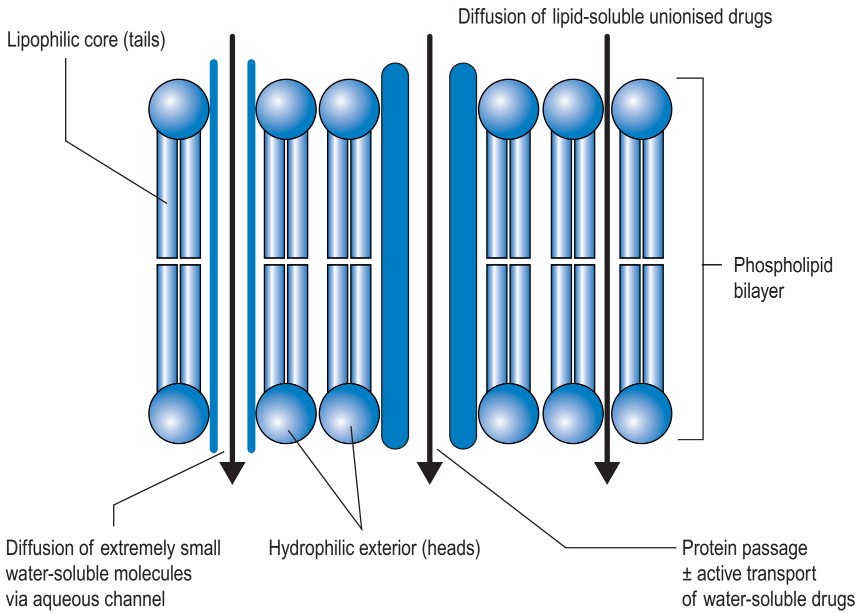

Figure 87.1 Diagram of a membrane.

- extent of first-pass metabolism (see metabolism), which can significantly reduce the amount of drug reaching the systemic circulation or lead to drug toxicity if the liver is failing.[7]

Intramuscular (i.m.) and subcutaneous (s.c.)

The effects via i.m. or s.c. can be erratic and unpredictable depending on local blood flow to tissues, adipose and muscle mass. Muscle perfusion is often significantly reduced in patients with haemorrhagic shock making it an undesirable route of administration if rapid systemic effects are required. Also, patients with a coagulopathy may be at increased risk of bleeding from the i.m. injection site.

Intravenous (i.v.)

The most common form of drug administration in ICU as it usually guarantees 100% bioavailability. However, several factors can still affect drug efficacy:

- drug–drug incompatibility when drugs of very different pHs are administered via the same i.v. line, e.g. propofol (near neutral pH) and atracurium (acidic pH)[8]
- drug–diluent incompatibility when a very acidic drug (e.g. amiodarone) is diluted with sodium chloride 0.9% (near neutral pH)[9] or a very basic drug (e.g. furosemide) is diluted with dextrose 5% (weakly acidic).[10]

The resultant salt-formed precipitates can lead to line occlusion, loss of drug efficacy and possible danger of systemic embolisation.

- Temperature and light can lead to degradation of, e.g., parenteral nutrition,[11] or sodium nitroprusside to cyanide ions,[12] which explains the need for an opaque covering.
- Too much diluent (e.g. amiodarone diluted beyond 0.6 mg/L comes out of solution, leading to loss of efficacy).[9]

DISTRIBUTION

Volume of distribution (V_d) is the theoretical volume of fluid into which the total drug administered would have to be diluted to produce the concentration in plasma. It is unrelated to volume of the body or its fluid compartments but rather its distribution.[13] V_d is increased by factors decreasing plasma drug concentration:[1]

- reduced protein binding (increased drug available for tissue binding)
- increased tissue binding
- increased lipid solubility (for fat-soluble drugs)
- oedema, ascites, effusion fluid (for water-soluble drugs)
- sepsis (endothelial damage and increased capillary permeability where fluid leaks into the interstitial space)
- mechanical ventilation (for water-soluble drugs),

and vice versa.

$$V_d = \frac{A}{C} \tag{87.1}$$

where V_d = apparent volume of distribution (L), A = total amount of drug in organ (mg), C = plasma concentration of drug (mg/L).

For example, gentamicin, a hydrophilic drug with minimal protein binding, has a low V_d similar to the extracellular fluid volume (0.25 L/kg).[14] In a septic, mechanically ventilated patient, the V_d of gentamicin increases as the effective extracellular volume increases, and a larger dose is required to obtain therapeutic levels.[15,16]

Phenytoin, a lipophilic drug, is 90% protein bound with a V_d similar to total body volume (0.65 L/kg).[1] Hypoalbuminaemia in critical illness increases the free, pharmacologically active fraction of phenytoin. This should be taken into account when interpreting phenytoin levels. The latter is normally reported as total serum concentrations that assume normal protein binding.

Morphine extensively binds to tissue and has a high V_d (4 L/kg).[17] Uraemia displaces drugs such as morphine from their tissue-binding sites, thereby increasing their plasma concentration whilst reducing the V_d, and this can lead to toxicity.

A drug with a high V_d will take considerable time to reach organ equilibration (approximately four to five times the half-life):[1]

$$t_{1/2} = 0.693 \times V_d / Q \tag{87.2}$$

where Q=organ blood flow.

V_d is used to calculate the *loading dose* (L_d), that is, the dose required to rapidly achieve a desired therapeutic concentration (C_p) of drug:

$$L_d = \frac{V_d \times C_{pss}}{S \times F} \tag{87.3}$$

where C_{pss}=desired plasma concentration at steady state, S=salt factor of drug, F=bioavailability as a fraction.

For example, the L_d of phenytoin sodium for a 70-kg patient via the i.v. route would be:

$$\begin{aligned} L_d &= \frac{0.65\ \text{L/kg} \times 70\ \text{kg} \times 15\ \text{mg/L}}{0.92 \times 1} \\ &= 741.8\ \text{mg} \end{aligned}$$

The dose is usually rounded to the nearest easily measurable value (i.e. 750 mg in this case). (**NB** This differs considerably from the standard 15 mg/kg dose often used in emergency practice where other prior antiepileptic medicines may have been given.)

Critically ill patients sometimes demonstrate subtherapeutic levels of phenytoin despite accounting for the unbound fraction due to hypoalbuminaemia. A possible explanation is that, as there is more of the free fraction available, more is available for metabolism and excretion. Alternatively, reduced hepatic function may lead to accumulation.[18]

Blood–brain barrier (BBB)

A combination of narrow junctions between the endothelial capillary cells and inherent resistance to the penetration of polar substances allows only the passage of lipophilic drugs via the transcellular route. Proteins, and therefore protein-bound drugs, are too large to cross. Conversely, drugs with low protein binding are able to penetrate the BBB.

In some cases active transporters prevent certain drugs from crossing the BBB. For example, loperamide is an opioid with no central effect at therapeutic doses as P-glycoprotein (an acute phase protein) excludes it from the brain. Conversely, in hepatic encephalopathy, damage to the BBB allows penetration of higher than normal amounts of opioids and, therefore, the patient's sensitivity to the drug's effects increases.

METABOLISM

Metabolism can occur using either or both of the following:[19]

- *Phase I reactions:* these involve addition or exposure of a polar group, for example –OH. Oxidation or reduction reactions in liver microsomes are catalysed by cytochrome P-450 (CYP) enzymes and hydrolysis of esters to alcohol and carboxylic acid by esterases.
- *Phase II reactions:* these increase a drug's hydrophilicity, promoting its renal or biliary excretion. Conjugation or synthesis takes place in the liver or the lung (e.g. glucuronidation, sulphation, acetylation, methylation). The kidney can excrete the drug metabolite by both filtration, and potentially, also by active secretion, into the urine. Usually metabolites are less active than their parent compound, more polar and more readily excreted in bile or urine.

Extensive first-pass metabolism refers to a drug that is significantly metabolised by the liver prior to becoming available to the systemic circulation.

ELIMINATION

CLEARANCE IN AN ORGAN

The liver and the kidney are the main organs involved in drug removal from the body. The liver can either transport a drug from the blood into the bile or metabolise it into another chemical entity (metabolite).

The rate (R) that the liver or kidney can remove drug from the body is usually proportional to the concentration of drug in the blood (C) (first-order kinetics). This proportionality constant is known as the drug's clearance (Cl) (**Fig. 87.2**).

Clearance is related to the half-life ($t_{1/2}$) of the drug.

Half-life is the time taken for the plasma drug concentration to fall by 50% and is dependent on V_d:

$$t_{1/2} = \frac{0.693 \times V_d}{Cl} \tag{87.4}$$

(Note: alpha $t_{1/2}$ refers to the distribution $t_{1/2}$; beta $t_{1/2}$ refers to the terminal elimination $t_{1/2}$.)

Figure 87.3 shows the graph of alpha and beta $t_{1/2}$.

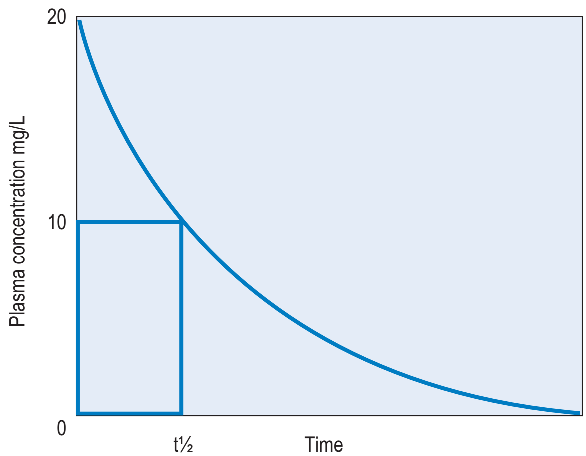

Figure 87.2 First-order elimination graph (plasma drug concentration versus time).

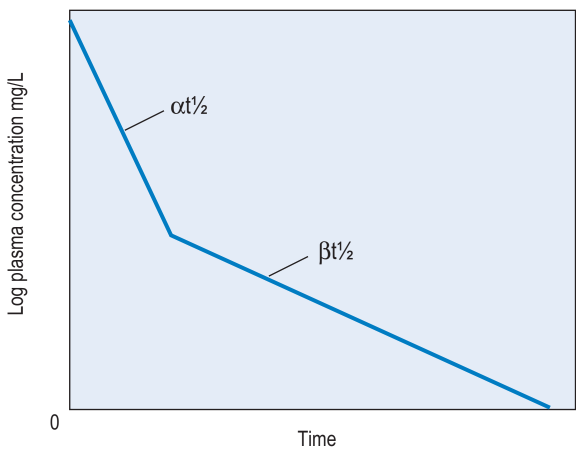

Figure 87.3 Graph of $\alpha\ t_{1/2}$ and $\beta\ t_{1/2}$.

Any process that reduces V_d without affecting clearance will shorten $t_{1/2}$ and vice versa.

$t_{1/2}$ can also be expressed as an equation involving the elimination rate constant (fraction of total drug removed per unit time):

$$k = \frac{Cl}{V_d} \tag{87.5}$$

This assumes the drug follows first-order kinetics (i.e. Cl and V_d do not change with dose or concentration).

Caution must be taken with interpreting half-lives with respect to a drug's duration of action. Simply using terminal elimination $t_{1/2}$ to predict the length of drug effect may not be accurate. For example, lipophilic fentanyl exhibits a three-compartment pharmacokinetic model post an i.v. bolus:[20]

1. *Short-distribution phase:* high concentrations are achieved rapidly in well-perfused organs (brain, kidneys, lungs)
2. *Slower redistribution phase:* in other tissues, skeletal muscle, fat
3. *Elimination phase.*

The terminal $t_{1/2}$ is 3.7 hours, but the duration of action of fentanyl may vary due to 80% protein binding (see effects of hypoalbuminaemia above) and redistribution into body compartments. Hepatic impairment prolongs $t_{1/2}$.

Steady state

$t_{1/2}$ can be used to predict the time for a drug to reach 'steady state' (i.e. when the rate of drug administered equals the rate it is eliminated). Usually this is reached within 4 or 5 half-lives. Similarly, the time taken for a drug to be eliminated from the body would also be 4 to 5 half-lives. A drug that is 90% dependent on metabolic clearance compared with 10% renal will, in hepatic failure, be eliminated primarily by the renal route, but total clearance will still remain at 10% so accumulation will occur.

Hepatic drug clearance

Hepatic drug clearance is affected by blood flow to the liver and the fraction of drug removed as it passes through – that is, the extraction ratio (ER):[19]

$$\mathrm{ER} = C_{\mathrm{in}} - C_{\mathrm{out}} / C_{\mathrm{in}} \tag{87.6}$$

where C_{in}=concentration in; C_{out}=concentration out.

- *High-extraction drugs (>0.7) e.g. morphine:* have significant first-pass metabolism and low oral bioavailability: There is a relative excess of the enzymes that metabolise a drug (i.e. a high intrinsic clearance) and a high proportion of the drug is removed by the liver before reaching the systemic circulation. The rate-limiting step is supply of the drug to the liver. Hepatic clearance therefore depends on hepatic blood flow, which is proportional to cardiac output,[21] and is unaffected by changes in the amount of active enzyme (and therefore enzyme inhibition or enzyme induction) and changes in free fraction of the drug. In advanced sepsis the hepatic blood flow is reduced, but in hyperdynamic sepsis the hepatic perfusion may be spared as blood is diverted to vital organs.

  Conversely, in cirrhosis, functional hepatocytes are bypassed when intrinsic clearance falls or portosystemic shunts form, both of which increase drug bioavailability.
- *Intermediate-extraction drugs pharmacokinetics (0.3–0.7) e.g. midazolam:* are more complex to predict. Drugs that fall into this category include those that are normally in the high ER group but alter in this respect when used in patients with hepatic dysfunction. Hepatic dysfunction and reduced metabolism lead to accumulation of active drug. This is further enhanced if drug metabolites are also active.
- *Low-extraction drugs (<0.3) e.g. lorazepam:* have negligible first-pass metabolism and high oral bioavailability: There is a relative deficit of enzymes that

Box 87.1 High and low extraction ratio (ER) drugs

High ER	Low ER
Propranolol	Lorazepam
Morphine	Theophylline
Fentanyl	Chlordiazepoxide
Amitriptyline	Phenytoin

metabolise the drug (i.e. a low intrinsic clearance) and the rate-limiting step is enzymatic activity. Hepatic clearance is independent of hepatic blood flow but is influenced by enzyme inhibition or enzyme induction, other competing drugs and changes in free fraction of the drug (the form accessible to the enzyme). Reduced liver perfusion and a fall in ER do not significantly affect drug bioavailability.

- Hepatic dysfunction can reduce the effects of pro-drugs that require metabolism to become active.

Box 87.1 lists high and low hepatic extraction drugs.

Zero-order metabolism Most drugs follow first-order pharmacokinetics (i.e. rate of metabolism correlates proportionally with plasma concentration). However, drugs such as phenytoin follow zero-order pharmacokinetics. In this situation metabolism reaches its peak as the enzyme system is saturated and relative clearance falls as plasma concentrations rise. The process is concentration-independent and so an increase in dose will produce a disproportionate rise in plasma levels. The rate of metabolism is constant regardless of the amount of drug present (**Fig. 87.4**).

Renal drug clearance[22]

Renal clearance of a drug or metabolite is influenced by glomerular filtration, tubular secretion and tubular reabsorption.

Glomerular filtration usually allows the passage of the free but not protein-bound drug into the renal tubules. Drugs that are not subject to tubular secretion or reabsorption therefore have a renal clearance that equals the glomerular filtration rate. For a healthy 70-kg 20-year-old man this is normally 0.1 L/min (i.e. a relatively low clearance rate is achieved). Conversely, drugs that undergo active tubular secretion can have higher renal clearances up to a theoretical maximum of renal blood flow (1.2 L/min). Such drugs are usually charged and can have a high affinity for transporter sites, which allows the passage of even protein-bound drugs. Tubular secretion normally occurs in the proximal tubule and is assumed if clearance rate exceeds calculated filtration rate.

Tubular reabsorption involves the passive diffusion of drugs back across the tubule into the systemic circulation. Such drugs are usually lipophilic and uncharged. The extent of reabsorption is determined by degree of ionisation and concentration gradient determined by urine pH and flow rate respectively. Reabsorption is

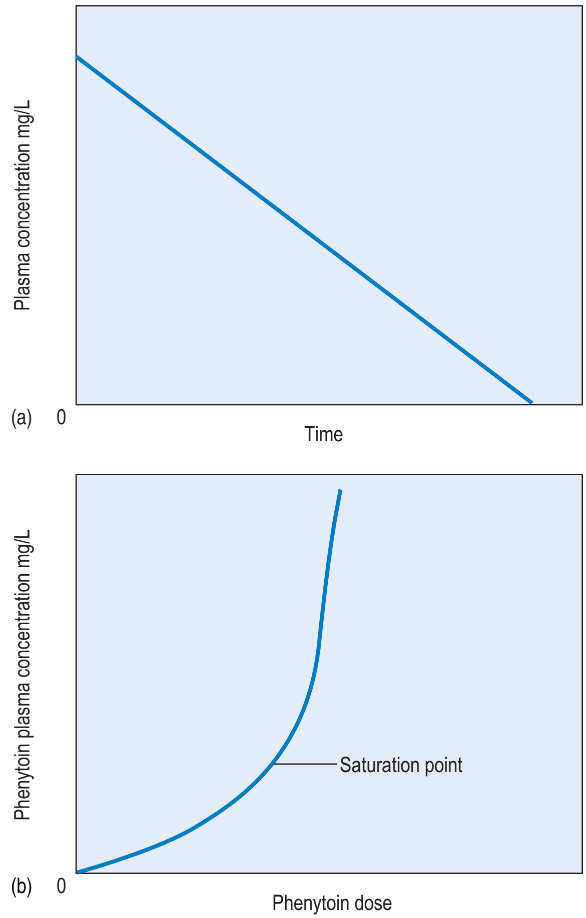

Figure 87.4 (a) Zero-order elimination. (b) Saturation point phenytoin pharmacokinetics.

assumed if clearance rate is less than calculated filtration rate (e.g. fluconazole reabsorption is considerable in normal renal function but reduced in acute kidney injury, therefore, dose reduction is not necessary or even an increase may be warranted).

Biliary clearance[1,3]

Large molecules can be actively transported by hepatocytes and excreted in the bile either unchanged or conjugated. Conjugated molecules can undergo enterohepatic recirculation (i.e. be hydrolysed by gut bacteria, secreted into the ileum, reabsorbed into the systemic circulation and transported back to the liver via the portal vein). Phenytoin and loperamide are examples of drugs that undergo significant enterohepatic circulation. Biliary obstruction will increase levels of active drug and metabolites excreted via this route.

Other drug clearance routes

Atracurium is an example of a drug that is independent of hepatic or renal clearance and is eliminated via two non-oxidative routes to inactive metabolites:[23]

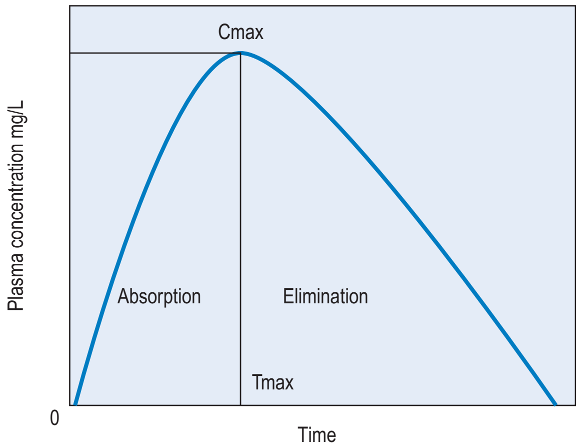

Figure 87.5 Areas under the curve (AUC).

1. Hydrolysis by non-specific blood esterases in the blood
2. The main route, a non-enzymatic pathway (Hofmann elimination) occurring at physiological pH and body temperature; the elimination rate is increased at higher pH or temperatures and vice versa.

DOSE–RESPONSE RELATIONSHIPS

The majority of drugs produce an effect by binding to a receptor,[1] usually an enzyme or membrane ion channel. A conformational change occurs producing a direct physiological response, the extent of which is dependent on the:

- number of receptors present
- affinity of drug for the receptor
- presence of agonists/antagonists competing for the receptor-binding site
- concentration of the free (unbound) drug within the vicinity of the receptor.

Drugs achieve a maximum effect as there are only a finite number of receptors upon which to act. A graph of plasma concentration of drug versus time is shown in **Figure 87.5**.

- C_{max} is the maximum plasma concentration achieved during the time course of the drug.
- T_{max} is the time taken to achieve C_{max}.
- $t_{1/2}$ is the time taken for the plasma level to fall by 50%.
- k is the elimination rate constant.

PHARMACOKINETIC MODELS

The ability to predict the effects of dose changes on concentration and outcome requires a mathematical representation or model of the behaviour of the drug. A model is defined by a set of equations (representing the basic structure) and a set of parameter values for those equations (representing the behaviour of a specific drug).

There are three basic forms of pharmacokinetic models:

- *Compartmental models* are the most commonly utilised. The body is represented by a central compartment plus one or more peripheral compartments. Drugs used in anaesthesia usually follow a three-compartment model: one compartment that is central, one that is slowly equilibrating and the other that is rapidly equilibrating (**Fig. 87.6**). As blood flow is not taken into account, compartment models have limited use in the critically ill where patient physiology is variable.
- *Physiological models* represent the major body organs. Drug supply to and from organs is influenced by vascular anatomy and organ perfusion. Animal models tend to be used as they are far easier to develop than human models (with some notable exceptions[24]). They are able to predict the consequences of changes in both dose regimen and physiological status.
- *Recirculatory models* are an intermediate between compartment and physiological models. They can provide a simple conceptual framework for the important relationship between cardiac output, bolus injection rate and initial drug concentrations[25] that is lacking in compartmental models.

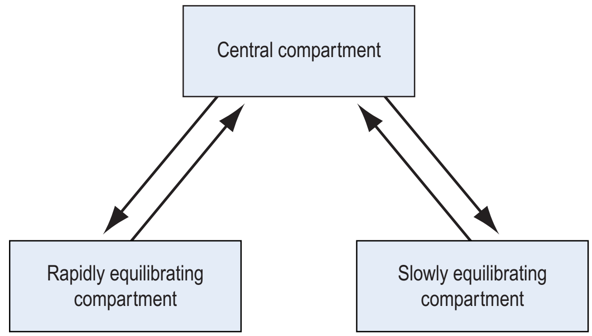

Figure 87.6 Compartment models.

More recently, population modelling aims to take into account patient variability with respect to physiology and pharmacological response to a given drug.[26]

TITRATION

The majority of drugs used in intensive care are relatively rapid in onset with a direct measurable effect. The dose can, therefore, be titrated to desired therapeutic outcome. Although titration can be empirical, optimal titration strategies are guided by an understanding of drug kinetics and dynamics. Important points to consider include:

- time required for the drug to achieve peak effect after an i.v. bolus; multiple doses within this time period may result in 'overshooting' the desired outcome
- potential dose range for titration
- time to offset of effect
- influence of evolving pathophysiology and tolerance on drug effect
- potential kinetic and dynamic interactions with co-administered drugs.

PRACTICAL APPLICATIONS

BOLUS INJECTION RATE

The rate of injection is often important to avoid toxic effects. Ranitidine can cause asystole and bradycardia if administered too fast – that is, greater than 25 mg/min.[27] Conversely, an 'i.v. push' refers to a rapid i.v. bolus; for example, adenosine is administered over 2 seconds due to its short half-life (less than 10 seconds).[28] If the time over which an i.v. bolus dose is not specified, it would be prudent to assume the drug should be administered over at least 3 minutes (i.e. as a slow i.v. bolus).

REPEAT BOLUS OR INFUSION

Drugs with relatively long half-lives and wide therapeutic indices can be administered by repeat bolus administration (e.g. ceftazidime); those with short half-lives and narrow therapeutic indices (e.g. catecholamines) should be administered in a more predictable and titratable manner by continuous infusion.

MAINTENANCE DOSE

ALTERING INFUSION RATES

The consequence of altering drug infusion rates is dependent on the half-life of the drug. If the half-life is relatively long (e.g. midazolam and morphine), an increase in dose requirements should be met by titrating small boluses to achieve the desired goal, and then increasing the infusion rate by the appropriate amount. Decreases in requirements can be met by stopping the infusion and recommencing at a lower rate after the new desired state has been reached. If severe illness causes the volume of distribution of a drug to be doubled then its half-life will also be doubled. Severe illness may also decrease clearance of a drug; halving clearance will cause a similar doubling of half-life. Should both effects occur together, half-life will be increased fourfold, having a significant effect on the duration of action of a drug.

OFFSET TIMES

The half-life for some drugs depends on the duration of the infusion (e.g. fentanyl's half-life increases with duration of continuous infusion). This is particularly evident for drugs with high distribution volumes and with bolus kinetics governed significantly by redistribution rather than clearance. For short infusions, the plasma half-life after the infusion will be less than the terminal elimination half-life. However, as the duration of infusion becomes sufficient to achieve steady state, the half-life upon stopping the infusion will increase until it equals the terminal elimination half-life.[29]

PK–PD CHANGES IN CRITICAL ILLNESS

Multi-organ failure significantly alters drug kinetics and dynamics making prediction of effects a therapeutic challenge.

CIRCULATORY FAILURE

Circulatory failure diverts blood flow to essential organs such as the heart and brain at the expense of the peripheral tissues. This results in:

- increased levels of drug in the heart and brain
- decreased levels of drug in the peripheries
- reduced renal blood flow and shunting of blood from cortical to juxtamedullary nephrons; glomerular filtration rate and tubular excretion fall, decreasing extraction of drugs and renally excreted metabolites
- reduced hepatic blood flow; liver function may be impaired, decreasing clearance of both highly extracted drugs (reduced delivery to the liver) and of poorly extracted drugs (reduced cellular metabolism).

Mechanical ventilation may cause further decline in hepatic perfusion by increasing intrathoracic pressure and therefore decreasing venous return.

The initial effect is a large decrease in distribution volumes and clearance of drugs. The effects are more profound on drugs that are usually rapidly distributed such as sedatives. Fluid and inotropic therapy may alter these effects over brief periods of time. With volume overload, there may be an increase in initial distribution volume (of water-soluble drugs) but with a more prolonged distribution half-life.

HEPATIC FAILURE

Drug dosing in hepatic failure is more difficult to predict compared with renal failure. Derangements in liver function tests do not usually serve as a strict guide for the extent of dose reduction compared with trends in creatinine clearance and other parameters used to estimate renal function.

Liver failure significantly affects the pharmacokinetics of drugs.

Absorption

Bioavailability of lipid-soluble drugs is reduced in cholestasis where bile salts are used to enhance their absorption.

Distribution

Patients with ascites may require larger loading doses of water-soluble drugs due to increased V_d.

Hypoalbuminaemia as a result of catabolism, sepsis, reduced protein intake and synthesis leads to an increase in free fraction of highly albumin-bound drug (e.g. phenytoin). Total serum concentration may appear low or within range but lead to toxic effects if the pharmacologically active free fraction is unaccounted for. Conversely, increased concentrations of α_1-acid glycoprotein (an acute-phase glycoprotein often raised in sepsis), to which phenytoin is 20% bound, can decrease the free fraction.[18] Phenytoin, therefore, exhibits complex and sometimes unpredictable pharmacokinetics in the critically ill.

Metabolism

(See extraction ratio (ER).)

Elimination

Cholestasis can reduce elimination of active drug or their metabolites that undergo biliary excretion and enterohepatic circulation. Concomitant renal dysfunction as in hepatorenal syndrome may require a dose reduction of renally excreted drugs.

RENAL FAILURE

Absorption[16]

Uraemia has been linked to reduced gut integrity in animal studies.

Certain drugs used in, for example, chronic renal failure, such as phosphate binders, can reduce the enteral absorption of certain drugs (e.g. ciprofloxacin).

Distribution[16]

Significant fluid retention due to volume resuscitation or reduced diuresis increases the V_d and, therefore, distribution $t_{1/2}$ of water-soluble drugs (e.g. gentamicin and beta lactams).

Reduced plasma protein binding of acidic drugs (e.g. amiodarone) can occur. Possible explanations include the displacement of acidic drugs from their albumin-binding sites by endogenous substances that accumulate in renal failure and compete for a position (see Metabolism below).

Plasma protein binding for basic drugs (e.g. epoprostenol) is not usually affected; however, certain interventions such as haemodialysis can raise levels of α_1-glycoprotein, an acute-phase protein to which basic drugs usually bind.[21]

If the unbound fraction of a drug increases and intrinsic clearance remains constant, plasma clearance will increase proportionally. Total plasma concentration will fall but the unbound plasma concentration will not be affected (e.g. phenytoin).

Reduced tissue binding can occur in end-stage renal failure (ESRF) causing a decrease in V_d.

Metabolism

Certain drugs that are mainly or completely eliminated from the body by non-renal mechanisms can still accumulate in renal dysfunction. This implies that their metabolism is impaired by renal failure. Possible explanations for this include reduced activity of metabolic enzymes.[22]

Accumulation of metabolic products can reduce protein binding of drugs. For example, uraemia displaces penicillins, sulphonamides and cephalosporins from their binding sites. The reduced affinity of plasma proteins for phenytoin increases the drug's free fraction. Therefore, a non-uraemic patient with a normal free fraction of phenytoin of 0.1 and a total phenytoin level of 7 mg/L will have the same free phenytoin concentration as a uraemic patient with a free fraction of 0.2 and a total phenytoin level of 14 mg/L:[1]

$$C_{\mathrm{paj}} = \frac{\text{total phenytoin level (mg/L)}}{0.9 \times (\text{albumin level}/\text{normal albumin level}) + 0.1} \quad (87.7)$$

where C_{padj} = adjusted phenytoin level (free phenytoin concentration), and normal albumin = 40 g/dL.

Elimination

Reduced renal clearance prolongs the terminal elimination $t_{1/2}$.

Renal failure can lead to toxicity if dose adjustments are not made to account for accumulation of drugs and their active metabolites cleared primarily by the kidneys. Dose can either be reduced, for instance vancomycin (time-dependent bacterial kill) or their dosing intervals increased, for instance gentamicin (concentration-dependent kill). Renal failure usually affects glomerular function more than tubular function so excretion of aminoglycosides, which depend more on glomerular filtration, is affected more than that of penicillins, which are dependent on tubular function.

Serum creatinine is usually a poor guide to renal function in the critically ill because creatinine is:

- a by-product of muscle often reduced in critical illness, the elderly or low-weight patients
- influenced by diet (recent protein intake, which can often be insufficient due to variable absorption if administered via the gastrointestinal tract)
- increased or reduced by drugs or disease states without necessarily influencing GFR (e.g. trimethoprim inhibits the renal secretion of creatinine without reducing renal clearance)
- used to calculate C_rCl based on a normal population data of healthy individuals
- usually fluctuating in the critically ill
- a very late marker of renal dysfunction – the GFR has to fall by at least 50% before a significant rise in creatinine is seen; it is better to monitor levels for accumulation of renally cleared drugs (e.g. vancomycin) or electrolytes (e.g. potassium).

Renal replacement therapy drastically alters volumes and clearances of drugs. Effects vary with the mode of dialysis, the filter life, the type of membrane in use and the drugs in question.

RESPIRATORY FAILURE

Insufficient gaseous exchange can disrupt the normal acid–base balance and consequently affect protein binding and V_d. Mechanical ventilation increases intrathoracic pressure, reducing cardiac output, hepatic and renal perfusion. Therefore, drugs with a high extraction ratio or those that are predominantly renally cleared may be at risk of accumulation. The V_d of water-soluble drugs (e.g. aminoglycosides) and the risk of a stress ulcer are also increased by mechanical ventilation.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

In sepsis and multi-organ failure, an increase in capillary permeability and a tendency towards increased total body water occurs, associated with hypoalbuminaemia. Larger loading doses are required to achieve the desired therapeutic response due to the consequent increased V_d of many drugs. Similar changes occur in patients with major burns. The volume of distribution may also change over short periods of time. When patients start to recover, serum concentrations may increase because of the decreasing volume of distribution of the drug (e.g. vancomycin[30]) as well as decrease because of resumption of normal metabolism and clearance (e.g. midazolam[31]). Circulatory, hepatic and renal failure may also add the characteristic changes already described, of decreased clearance or metabolism and accumulation of active metabolites.

The consequence of hypoalbuminaemia on highly protein-bound antibiotics

Hypoalbuminaemia increases V_d by increasing the free fraction of drug in the extracellular compartment. Unbound drug leaves the systemic circulation to distribute to tissues and total drug concentrations fall in the intravascular compartment; that is, there is a fall in total effective serum concentrations over time (area under the curve). The consequences of this include:

- reduced time above the MIC for time-dependent antibiotics
- reduced C_{max}/MIC for concentration-dependent antibiotics.

Continuous vancomycin infusions are often used in ICU. This is a more convenient method of administration for the time-dependent antibiotic as levels can be taken at any time post steady state (see 'sampling time for drug levels'). In contrast, once-daily dosing of relatively larger doses of gentamicin (as opposed to smaller doses administered more frequently) are used to optimise its concentration-dependent kill whilst minimising accumulation risk. Therapeutic drug monitoring (TDM) guides dosing (see TDM), but for other antibiotics with wider therapeutic indices, such as caspofungin, TDM is not routinely performed. Dosing should ideally be at the maximum dose possible whilst avoiding accumulation (usually manifested as an accentuation of the drug's usual side-effects). Extended infusion times of beta lactam antibiotics beyond the manufacturer's licensed duration (e.g. meropenem) have been shown to achieve better pharmacodynamics targets against less susceptible microorganisms such as *P. aeruginosa* and *Acinetobacter*[15,32] (**Box 87.2**).

An increased $t_{1/2}$ is caused by redistribution of drug from the tissues to blood. This is beneficial in both time- and concentration-dependent antibiotics with high susceptibility (i.e. it increases the time above the MIC).

Box 87.2 Highly protein-bound and minimally protein-bound antibiotics

Highly protein bound	Minimally protein bound
Amphotericin B 90%	Gentamicin <30%
Caspofungin 97%	Vancomycin 10–50%
Ceftriaxone 85–95%	Meropenem 2%
Teicoplanin 90–95%	Imipenem <30%

CHANGES IN RECEPTORS IN ACUTE ILLNESS

Catecholamines demonstrate increased receptor numbers in response to a lack of agonist (up-regulation) and reduced receptor numbers in the presence of excess agonist (down-regulation). Drug affinity for receptors is also influenced by pH. Acidosis decreases the affinity of catecholamines for their receptors, and becomes a clinically significant problem when there is a pH<7.1. Body temperature also affects pharmacodynamics – hypothermia decreases drug affinity for receptors.

Proliferation of extrajunctional acetylcholine receptors on muscle after acute injuries such as burns and denervation can lead to hyperkalaemia following the use of suxamethonium.

THERAPEUTIC DRUG MONITORING (TDM)

TDM is used to guide dosing of drugs with a narrow therapeutic range (i.e. a small therapeutic to toxic window) – for example gentamicin, phenytoin and theophylline. Toxicity may be associated with peak drug concentrations (e.g. seizures and arrhythmias from theophylline) or with mean concentrations (e.g. ototoxicity from aminoglycosides). **Table 87.1** displays examples of drugs with a narrow therapeutic window.[33–35] Hospital laboratories measure total plasma drug concentration. However, it is the unbound drug fraction that is pharmacologically active (see phenytoin).

Regardless of measured concentration, evidence of clinical efficacy or toxicity must be monitored regularly (e.g. altering the maintenance dose of digoxin in a patient with a subtherapeutic level is unnecessary if ventricular rate is adequately controlled). Conversely,

Table 87.1 Therapeutic drug monitoring in the critically ill

DRUG	THERAPEUTIC CONCENTRATION	TOXIC EFFECTS
Digoxin	1–2 μg/L	CNS and visual disturbances, dizziness, nausea and vomiting[1]
Gentamicin	<1 mg/L (trough)	Nephrotoxicity, ototoxicity[14]
Amikacin	<5 mg/L (trough)	Nephrotoxicity, ototoxicity[33]
Vancomycin	20–25 mg/L (continuous infusion)	Nephrotoxicity, ototoxicity, reversible neutropenia[34]
Phenytoin	10–20 mg/L	Nystagmus, ataxia, dysarthria, cardiovascular collapse[5] Correct for hypoalbuminaemia Caution in uraemia
Theophylline	10–20 mg/L	Arrhythmias, nausea, vomiting[35]

it would be prudent to reload a previously stable epileptic patient presenting with seizures if the phenytoin level is subtherapeutic. If the phenytoin level is therapeutic and the patient's convulsions persist, a neurology review is required. This usually results in addition of, or change to, another agent.

SAMPLING TIME FOR DRUG LEVELS

The ideal sampling time for a drug level is either just prior to the next due dose or once distribution into the tissue is known to be complete. If taken prior to distribution, the levels will be falsely interpreted as higher than expected for the dose administered. For example, an i.v. loading dose of phenytoin takes at least 2 hours for distribution.[1] A level taken prior to this time would not be a true reflection of the dose administered and subsequent dosing based on the result will be incorrect.

The majority of drug levels are obtained as a 'trough' – that is, a pre-dose level as suggested in the case of phenytoin. Usually, levels should not be taken prior to steady state being reached; for example, it would take approximately 10 days following a formulation change for phenytoin to reach steady state. However, if the patient's pharmacokinetics is suspected not to follow the normal population, as in the case of the critically ill, and if there is a risk of accumulation or underdosing before this time, it would be prudent to sample much sooner so the dose can be promptly optimised.

THE EFFECT OF DRUG INTERACTIONS ON PHARMACODYNAMICS

Multiple drug therapy in the critically ill increases their vulnerability to the effects of drug interactions. It could also be argued that ICU patients are monitored more closely than their counterparts on general wards so any adverse effects are likely to be identified sooner. Nevertheless, if a patient does not demonstrate a normal response to a drug treatment, it may be due to a drug interaction.

The consequence of drug interactions is naturally dependent on the drugs in question. **Table 87.2** provides a few examples of interactions involving commonly used drugs in ICU. Certain drugs (e.g. warfarin) are usually avoided altogether in the critically ill due to their numerous drug interactions, long $t_{1/2}$ and potentially catastrophic effects on coagulation in an already vulnerable patient with variable physiology.

SUMMARY

The relationship between PK and PD can be used to predict a dosing regimen for a patient. However, wide inter-patient variability and the labile nature of the critically ill means careful consideration needs to be applied when formulating an appropriate dose. Best clinical judgement is required. Treatment may need to be individualised and titrated, especially when the outcome does not follow the normal expected clinical response. Levels should be taken to guide dosing in drugs with narrow therapeutic windows but caution must be taken with interpretation, especially when the clinical symptoms do not correlate with apparently therapeutic readings. For drugs with 'silent' pharmacodynamics, other markers of therapeutic effect should be sought – for example, a reduction in temperature, C-reactive protein (CRP) and white cell count (WCC) in anti-infectives with a wide therapeutic index. At the same time, optimising dosage in ICU should take into account the adverse effects of accumulation if higher doses are used beyond what is normally recommended.

In line with non-drug therapies in the ICU, drug kinetic and dynamics are never simple or straightforward and rarely does one dosage regimen fit all. For further advice, please consult your pharmacist.

Table 87.2 Examples of drug–drug interactions in ICU patients

DRUG A	DRUG B	INTERACTION	COMMENT
Norepinephrine (noradrenaline)	Amitriptyline	Amitriptyline and related antidepressants block norepinephrine uptake into adrenergic neurons thereby potentiating its effect	Results in ↑ blood pressure and heart rate beyond what is usually expected
Midazolam	Amiodarone	Amiodarone is an inhibitor of cytochrome P450 isoenzyme by which midazolam is metabolised	Results in ↑ levels of midazolam
Midazolam	Fluconazole	Fluconazole is an inhibitor of cytochrome P450 isoenzyme by which midazolam is metabolised	Results in ↑ levels of midazolam
Haloperidol	Amiodarone	Both drugs prolong QT interval	Results in ↑ risk of ventricular arrhythmias
Phenytoin	Hydrocortisone	Phenytoin is a potent enzyme inducer	↑ Hydrocortisone metabolism, ↓Therapeutic and adrenal suppressant effects
Amiodarone	Simvastatin	Amiodarone is an inhibitor of cytochrome P450 isoenzyme by which simvastatin is metabolised	↑ Risk of myopathy

Management of acute poisoning

David M Wood and Duncan LA Wyncoll

Acute poisoning remains one of the commonest medical emergencies, accounting for 5–10% of hospital medical admissions. Although in the majority of cases the drug ingestion is intentional, the in-hospital mortality remains low (<0.5%).[1] There are specific antidotes available for a small number of poisons and drugs; however, in most intoxications, basic supportive care is the main requirement and recovery will follow. This chapter is a hands-on guide to the general management of acute poisoning and drug intoxication. For more detailed information than can be provided here, please refer to internet-based information services (e.g. Toxbase in the UK – http://www.spib.axl.co.uk) or a local/regional/national telephone poisons information service (e.g. National Poisons Information Service in the UK – 0844 8920111).

Clinical toxicology remains an experience-based specialty; consequently, many recommendations are based on a small literature of case reports, rather than controlled clinical studies. In recent years, toxicological experts have produced position statements and clinical guidelines on certain aspects of care, and these are referenced when possible.

GENERAL PRINCIPLES

The general principles of the management of poisoned patients are diagnosis based on history and clinical features, clinical examination, resuscitation, investigations and continued supportive care. Measures to reduce absorption or enhance elimination, and specific treatments, may be indicated in some cases. In the more acute situations, these actions often have to be carried out simultaneously.

ABC

In acutely poisoned patients who are unconscious, dentures should be removed and the oropharynx cleared of food and vomit. Tracheal intubation and airway protection is almost always necessary when a patient tolerates insertion of an oropharyngeal airway – perhaps the only exception to this rule is patients who have taken gamma hydroxybutyric acid (GHB) and gamma butyrolactone (GBL) (see later). Inadequate spontaneous ventilation, determined clinically or by arterial blood gas (ABG) analysis, obviously requires ventilatory support. Venous access should be established, and circulatory assessment must be made. Basic observations, including blood pressure, pulse rate, temperature, peripheral perfusion and urine output, should be recorded.

CLINICAL EXAMINATION

The clinical examination should include looking particularly for needle marks or evidence of previous self-harm. The Glasgow Coma Scale, designed for head-injured patients, is frequently used but descriptive documentation of the degree of impaired consciousness is much more valuable. In an unconscious patient with no history available, the diagnosis depends upon excluding other common causes of coma (**Box 88.1**) and circumstantial evidence. Specific attention should be paid to the temperature, pupil size, blood pressure, respiratory and heart rate, as these may help to restrict the list of potential toxins (**Box 88.2**). Patients should also have a detailed neurological examination, preferably before the administration of any muscle relaxants, documenting the presence/absence of abnormal tone and reflexes, spontaneous/inducible clonus and/or ocular clonus.

INVESTIGATIONS

Important initial investigations include the following:

- *Urinalysis*: keep a sample for later analysis if required. Although rapid reaction dipsticks are available to screen for common drugs of abuse/recreational drugs by immunoassay, their routine use is not recommended owing to false-positive results, detection of metabolites rather than parent drug and/or cross-reactivity with prescription and over-the-counter medicines.
- *Basic biochemistry*: many drugs are dependent on renal elimination. Significant renal insufficiency may alter management.
- *ABG analysis*: metabolic and/or respiratory acidosis is most common. Aspirin may initially cause a respiratory alkalosis, which in more significant ingestions can be followed by a metabolic acidosis or combined picture of a respiratory alkalosis/metabolic acidosis. Metabolic alkaloses are unusual.

Box 88.1 Common causes of coma other than acute poisoning

Intracranial bleeds
- Subarachnoid haemorrhage
- Subdural/extradural haematomas

Meningitis or encephalitis
Diabetic comas
Uraemic encephalopathy

Box 88.2 Clinical effects of the common poisons

Convulsions
Tricyclics, isoniazid, lithium, amfetamines, theophylline, carbon monoxide, phenothiazines, cocaine
Skin
Bullae: barbiturates, tricyclics
Sweating: salicylates, organophosphates, amfetamines, cocaine
Pupils
Constricted: opioids, organophosphates
Dilated: hypoxia, hypothermia, tricyclics, phenothiazines, anticholinergics
Temperature
Pyrexia: anticholinergics, tricyclics, salicylates, amfetamines, cocaine
Hypothermia: barbiturates, alcohol, opioids
Cardiac rhythm
Bradycardia: digoxin, beta blockers, organophosphates
Tachycardia: salicylates, theophylline, anticholinergics
Arrhythmias: digoxin, phenothiazines, tricyclics, anticholinergics

- *Anion gap* = $([Na^+]+[K^+])-([Cl^-]+[HCO_3^-])$: it is normally 10–14. Ethanol, methanol, ethylene glycol, metformin, cyanide, isoniazid or salicylates are the most frequent causes of a high anion gap metabolic acidosis in clinical toxicology.
- *Chest X-ray*: inhalation of gastric contents is not uncommon.
- *Drug levels*: these are rarely helpful except in specific poisonings. They include paracetamol, salicylates, iron, digoxin and lithium. It is important to note that, for most poisonings, drug concentrations guide rather than dictate treatment.

GUT DECONTAMINATION

EMESIS

Ipecacuanha-induced emesis is no longer recommended.[2] It is ineffective at removing significant quantities of poisons from the stomach, limits the use of activated charcoal and can increase the risk of aspiration in those patients who have a reduced level of consciousness.

Box 88.3 Drug intoxications where multiple-dose activated charcoal may be beneficial

Carbamazepine
Theophylline
Digoxin
Quinine
Phenobarbital
Dapsone
Sustained-release preparations

GASTRIC LAVAGE

The joint American and European toxicologists' statement suggests that gastric lavage removes an insignificant amount of poison, and may only propel unabsorbed poison into the small intestine; therefore it is no longer routinely recommended.[3] Additionally, it is important to note that gastric lavage often delays the use of activated charcoal, which is likely to have greater benefit with less unwanted effects or risks.

ACTIVATED CHARCOAL

Activated charcoal (AC) remains the first-line treatment for most acute poisonings.[4] Owing to its large surface area and porous structure it is highly effective at adsorbing many toxins with few exceptions. Exceptions include elemental metals, pesticides, alcohols including ethanol, strong acids and alkalis, and cyanide. It should be given to all patients who present within 1 hour of ingestion of a potentially toxic amount of a drug or drugs; it should not be given to those patients who are drowsy (unless they have a protected airway). International guidelines recommend administration of AC within 1 hour, so it is vital to identify rapidly those who present after a potentially serious overdose so that it can be given swiftly.[5] Longer than 1 hour it may still be effective if it follows an overdose of a substance that slows gastric emptying (e.g. opioids, anticholinergics, tricyclic antidepressants), but this depends on the clinical condition of the patient and amount ingested.

Repeated doses of AC can increase the elimination of some drugs by interrupting their entero-enteric and enterohepatic circulation.[6] Indications for repeated dose AC are shown in **Box 88.3**. It should be considered in patients who have ingested a modified or slow-release preparation or significant salicylate ingestions; in these situations multiple doses of AC are being administered to reduce absorption rather than enhance elimination. AC is given in 50 g doses for adults and 1 g/kg (max 50 g) for children. It commonly causes vomiting; therefore consider giving an antiemetic prior to administration. Multiple doses can be associated with constipation so patients should be given an appropriate laxative. Repeated doses are given at 4-hourly intervals until it is clinically indicated to stop.

WHOLE BOWEL IRRIGATION

This is a method of gut decontamination that is indicated for a limited number of poisons.[7] Whole bowel irrigation involves administration of non-absorbable polyethylene glycol solution to cause a liquid stool and reduce drug absorption by physically forcing contents rapidly through the gastrointestinal tract. Polyethylene glycol preparations are still occasionally used in surgical units for 'bowel preparation' prior to surgery. It may have a role in treating large ingestions of drugs that are not absorbed by AC. Indications include large ingestions of iron or lithium, ingestion of drug-filled packets/condoms ('body packers'), and large ingestions of sustained-release or enteric-coated drugs (e.g. theophylline or calcium channel blockers).

ENHANCING DRUG ELIMINATION

In the overwhelming majority of patients who present after an overdose, gut decontamination techniques and supportive care are all that is required. In a limited number of acute poisonings it may be necessary to consider methods to enhance elimination.

URINARY ALKALINISATION

Urinary alkalinisation (previously termed *forced alkaline diuresis*) may be useful for serious poisonings with:

- salicylates
- phenobarbital (with repeated dose AC)
- chlorpropamide
- methotrexate.

Intravenous 8.4% sodium bicarbonate is infused (the joint American and European toxicologists' statement recommends 225 mL over 1 hour in adults) to achieve a urine pH of approximately 7.5–8.5. The term 'urine alkalinisation' emphasises that urine pH manipulation is the prime objective of treatment; the terms 'forced alkaline diuresis' and 'alkaline diuresis' should be discontinued. According to international position statements it should be considered the treatment of choice for moderate to severe salicylate poisoning.[8] Care must be taken to ensure the potassium does not fall rapidly, and the urine pH should be measured every 30 minutes.

EXTRACORPOREAL TECHNIQUES

Numerous extracorporeal techniques are potentially available to aid drug removal in the poisoned patient, as well as correct metabolic and biochemical abnormalities as a result of the poisoning. These include plasmapheresis, haemodialysis, haemofiltration, haemodiafiltration and haemoperfusion. There are limited data on drug clearance by these techniques in the literature and it is not possible to extrapolate from one system to the other. At present, knowledge of the principles of the methods and the kinetics of the drug involved is relied upon.

Extracorporeal techniques should be considered only when there are clinical features or markers of severe toxicity, failure to respond to full supportive care coupled with poisoning by a drug that can potentially be removed. Impairment of the normal route of elimination of the compound may also influence the decision. Use of extracorporeal techniques is probably worthwhile only if total body clearance is increased by at least 30%. Haemoperfusion is rarely performed in most intensive care units and intermittent haemodialysis is often confined to renal units. Consequently, the use of continuous haemofiltration, with or without dialysis, using filtration rates of greater than 50–100 mL/kg per hour is likely to be as equally effective as when an extracorporeal technique is indicated.

An international multidisciplinary working party called EXTRIP (EXtracorporeal TReatments In Poisoning) is currently reviewing the role of extracorporeal elimination and will be issuing a number of guidelines for poisonings where extracorporeal elimination is used/considered shortly.[9]

LIPID EMULSION THERAPY

Intravenous lipid emulsion (ILE) is now recognised as an effective treatment for local-anaesthetic-induced cardiovascular collapse. The mechanism for benefit is not entirely clear, but is thought to relate either to the formation of an enlarged lipid sink, which may help to remove the offending drug from target tissues, or as an energy substrate for a shocked myocardium. Based on the lipid sink hypothesis, ILE has been considered a potential treatment for severe acute poisoning from a range of lipophilic drugs. There is good evidence from animal models and human cases/case series for its use in the management of local anaesthetic toxicity; there are an increasing number of case reports where ILE has been used in other poisonings, however, its use is not routinely recommended at this time. It is now frequently available in emergency rooms and other critical care settings. No optimal dosing regimen has yet been established, but it is clear that ILE has emerged as a possible powerful antidote in the last few years.[10] There have been reports of recurrence of toxicity after initial dosing with ILE, as well as complications such as pancreatitis.

CONTINUED SUPPORTIVE THERAPY

Self-poisoned patients do not always engender the empathy of the admitting medical team, but they are medical challenges, rather than merely instances of self-inflicted illness. Specific measures are described later, but good general supportive care of the unconscious unstable patient should be continued. This includes monitoring and provision of organ support when necessary, as well as fluid balance, correction of electrolytes, initiation of nutritional support, and prompt treatment of nosocomial infection.

Overall, in spite of the significant initial physiological disturbance, this group of patients usually has a good outcome.

SPECIFIC THERAPY OF SOME COMMON OR DIFFICULT OVERDOSES

This section emphasises only those features that may aid clinical diagnosis or prognosis. These are always intended to support those measures described under general principles. Some new and controversial therapies are mentioned.

AMFETAMINES (AMPHETAMINES) INCLUDING 'ECSTASY', MDMA

CLINICAL FEATURES

Symptoms of mild overdose include sweating, dry mouth and anxiety. Although the majority of ecstasy patients are dehydrated, a proportion have hyponatraemia from drinking water to excess; therefore it is important to measure serum sodium and electrolytes early in the patient's management. More severe features include tachycardia, hypertonia, hyperreflexia, hallucinations and hypertension. Supraventricular dysrhythmias may follow with coma, convulsions and the risk of haemorrhagic stroke. A hyperthermic syndrome may develop with hyperpyrexia leading to rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation (DIC) and multiple organ failure. Where hyperthermia is suspected it is important that core body temperature (e.g. rectal) is measured to accurately record the degree of hyperthermia.[11]

TREATMENT

AC should be considered up to 1 hour post ingestion. Benzodiazepines are useful for agitated or psychotic patients and may have a central effect in reducing tachycardia, hypertension and hyperpyrexia. If benzodiazepines fail to control hypertension, other classes of antihypertensives should be started, such as alpha blockers or direct vasodilators. Beta blockers, even specific ones, should not be used due to the risk of unopposed alpha stimulation and subsequent hypertension developing. It should be noted that most patients are fluid-depleted rather than fluid-overloaded, and measurement of sodium concentrations should be undertaken early in fluid resuscitation. Hypertonic saline may rarely need to be considered in severe hyponatraemia. Hyperthermia should be treated in the standard manner, including administration of cold i.v. fluids, general cooling measures and benzodiazepines. For patients whose temperature remains elevated (particularly above 39°C), consider PO/NG cyproheptadine (a $5HT_{2A}$ antagonist) – the initial dose is 12 mg followed by 2 mg every 2 hours until temperature and other symptoms have settled. Additional methods for cooling, such as external and internal cooling devices or those used for therapeutic hypothermia post cardiac arrest, can be considered for rapidly reducing body temperature. Benzodiazepines and cyproheptadine should also be used in those patients with evidence of moderate/severe serotonin toxicity.[12]

BENZODIAZEPINES

CLINICAL FEATURES

Overdose is common, but clinical features are not usually severe unless complicated by other CNS depressant drugs (such as alcohol), pre-existing disease or the extremes of age. Toxicity commonly produces drowsiness, dysarthria, ataxia and nystagmus. Paradoxical agitation and confusion can occur less commonly.

TREATMENT

AC can be given if patients present within 1 hour of ingestion, yet supportive treatment is usually all that is required. Flumazenil is a specific antagonist (not licensed for use in poisoning) – there is the risk of significant cardiovascular (ventricular tachycardias) and neurological (status epilepticus) toxicity, as well as precipitating withdrawal in benzodiazepine-dependent patients.[13] Its use is therefore not recommended.

BETA BLOCKERS

CLINICAL FEATURES

There is a wide variation in the individual response to beta-blocker overdose. Those with cardiac disease are more at risk of complications. Hypotension and bradycardia predominate and are often refractory to standard resuscitation measures. The degree of heart block can range from a prolonged PR interval through to complete heart block and asystole. Cardiogenic shock and pulmonary oedema are not uncommon.[14]

TREATMENT

AC should be considered up to 1 hour post ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. The role of atropine is not clear, although it is commonly used in patients who have bradycardia and hypotension. If symptomatic treatment with i.v. fluids for hypotension fails, glucagon (up to 10 mg i.v. as an initial bolus) is the next step. Further boluses and/or an infusion may be beneficial in addition to the initial bolus. Vomiting indicates that an 'adequate' dose of glucagon has been administered. Further options include hyperinsulinaemic–euglycaemic treatment, as described in the calcium channel blocker section is indicated. Inotropes and cardiac pacing (higher-voltage capture may be required) can be considered and based on the patient's clinical condition. Other measures such

as intra-aortic balloon pumps and extracorporeal support (e.g. ECMO, bypass) may be locally available.

BUTYROPHENONES (INCLUDING HALOPERIDOL)

CLINICAL FEATURES

Drowsiness and extrapyramidal effects are most common. Rarely hypotension, QT prolongation, arrhythmias and convulsions develop. Serious toxicity is uncommon.

TREATMENT

AC should be considered up to 1 hour post ingestion, otherwise treatment is supportive. Extrapyramidal symptoms can be treated with procyclidine (5–10 mg i.v./i.m. in adults) or diazepam (10–20 mg in adults).

CALCIUM CHANNEL BLOCKERS

CLINICAL FEATURES

The cardiac effects of these drugs predominate in overdose, particularly hypotension and atrioventricular block, although reflex tachycardia occurs with nifedipine. Hypotension occurs owing to peripheral vasodilatation and negative inotropy. The therapeutic selectivity of actions is not typically seen in overdose. Severe toxicity may occur in patients who initially appear well, when sustained-release preparations have been ingested.

TREATMENT

AC should be considered up to 1 hour post ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. Treatment remains supportive; however i.v. calcium chloride (10 mL of 10% solution) is often given in patients who remain hypotensive despite fluid administration. Further boluses and/or an infusion should be administered as guided by the clinical response. If calcium gluconate is used then administer 30 mL of 10% solution (it has one-third the ionised calcium compared with calcium chloride, and therefore doses should be increased by threefold where calcium gluconate is used). In those patients requiring multiple doses and/or an infusion, monitor the serum calcium concentration to ensure it remains below 3 mmol/L. Atropine is often used for bradycardia, and occasionally cardiac pacing may be necessary. In those with persistent hypotension not responding to i.v. fluids and calcium, the next step is hyperinsulinaemic–euglycaemic therapy is indicated.[15] An initial bolus of 1 unit/kg of short-acting insulin should be administered with 25–50 mL of 50% dextrose, followed by an infusion of 0.5–2 units/kg/h short-acting insulin; higher doses may be required in severely compromised patients. Careful monitoring of blood glucose and serum potassium should be undertaken, with replacement as necessary. There is anecdotal evidence that increasing glucose requirements suggest that the cardiovascular toxicity is starting to diminish.

CARBAMAZEPINE

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. Carbamazepine undergoes enterohepatic recirculation leading to a prolonged overall half-life and is metabolised to an active metabolite.

CLINICAL FEATURES

Nystagmus, ataxia, tremor and fits are common but, in severe overdose, fluctuating coma and severe tachycardia or bradycardia may occur. Plasma concentrations of carbamazepine and the active metabolite can be measured, although they do not correlate well with toxicity. Life-threatening toxicity typically occurs with plasma concentrations greater than 40 mg/L (170 nmol/L).

TREATMENT

Multiple-dose AC is indicated in large ingestions or symptomatic patients, and may help elimination even if initiated several hours after the overdose. Further measures are based on the clinical course.

CARBON MONOXIDE (CO)

Haldane first described symptoms of CO toxicity in 1919 and the mechanisms of toxicity remain unclear. Smokers may have up to 10% of their haemoglobin bound to CO (i.e. carboxyhaemoglobin, COHb) without deleterious effects. Whereas coma and/or COHb levels >40% always indicate serious poisoning, delayed deterioration can occur in their absence. Affinity of CO for haemoglobin is approximately 240 times that of oxygen.

CLINICAL FEATURES

Neurological signs vary from mild confusion through to seizures and coma. A history of loss of consciousness should always be sought and may be the only indicator of significant poisoning. ST segment changes may be present on electrocardiogram (ECG). In the absence of respiratory depression or aspiration, Pa_{O_2} will be normal. It is essential that Sa_{O_2} is measured directly by a co-oximeter, and not calculated. Cherry-pink skin is seen only in textbooks; cyanosis is far more common.

TREATMENT

After basic resuscitative measures, high-flow oxygen (up to 100% if possible) should be administered and continued until the COHb level is less than 5%. This sometimes takes up to 24 hours. Hyperbaric oxygen (HBO), although often used, remains controversial. There have been eight randomised controlled trials of

HBO versus normobaric oxygen. Unfortunately, many of these are of poor quality and it is not possible to show any statistical benefit of HBO in reducing neurological sequelae at 1 month.[16] Considering the frequently encountered logistical difficulties in transferring an unconscious patient to an HBO centre, it cannot be routinely recommended based on the data currently available.

CHLOROQUINE

CLINICAL FEATURES

Hypotension, hypokalaemia, convulsions, ventricular arrhythmias and sudden cardiac arrest may result from severe poisoning. As little as 2 g of chloroquine have been reported to be fatal in adults. Symptoms typically tend to occur very early following ingestion, and normally within 3 hours of ingestion.

TREATMENT

AC should be considered up to 1 hour post ingestion. In patients who have ingested potentially significant amounts of chloroquine or who have features of significant poisoning, then high-dose diazepam (2 mg/kg over 30 minutes) with inotropic and ventilator support should be considered.[17] Hypokalaemia is common and may be protective in the early stage. It is self-correcting and consequently aggressive potassium replacement is not recommended.

COCAINE

CLINICAL FEATURES

The clinical features of acute cocaine toxicity are similar to those seen in the amfetamine section above. There is the additional risk of cocaine-related vasospasm, which can lead to ischaemia in any vascular bed, but is of particular significance from a cardiac and cerebral perspective. Cocaine-related myocardial ischaemia is due primarily to coronary artery vasospasm; additional mechanisms included increased myocardial oxygen demand due to increased heart rate, decreased vasodilators (nitric oxide), increased vasoconstrictors (endothelin) and increased platelet aggregation.[18]

TREATMENT

The treatment of the common unwanted effects related to cocaine are the same as those seen with amfetamines as described above. In terms of myocardial ischaemia, there are some differences between the management of this compared with classical atherosclerotic-related ischaemia. Patients should be treated with oxygen and aspirin; low-molecular-weight heparin and glycoprotein IIb/IIIa inhibitors should not be routinely used – their use should be guided by the blood pressure (increased risk of cerebral haemorrhage in those with significant hypertension). Vasodilators (e.g. S/L, buccal or i.v. nitrates) should be given early in an attempt to reverse coronary artery vasospasm; they may be contraindicated if there is a significant tachycardia due to the risk of a reflex tachycardia leading to an increased heart rate. Benzodiazepines should be administered to reduce sympathetic nervous system stimulation, reducing myocardial oxygen demand by reducing heart rate, as well as potentially causing coronary artery vasodilatation through peripheral cardiac benzodiazepine receptors. Beta blockers are contraindicated as they can lead to unopposed alpha stimulation leading to worsening hypertension, and in addition they can worsen cocaine-related coronary artery vasospasm. Other measures in those who fail to respond include other vasodilators (e.g. calcium channel blockers, alpha blockers) and/or primary angiography and angioplasty/intraluminal drug treatment.

CYANIDE

CLINICAL FEATURES

Severe toxicity is rapidly fatal; however, features include coma, respiratory depression, hypotension and metabolic acidosis. More moderate features include brief loss of consciousness, convulsions and vomiting. Rescuers must ensure that they do not get contaminated themselves. Expert advice is usually required in the management of these patients owing to the risk of significant toxicity.

TREATMENT

Inhaled amyl nitrate and 100% oxygen may well have been given at the scene, since it is present in 'cyanide antidote kits'. Following this there are a number of options:

1. Patients with severe features need dicobalt edetate 300 mg i.v. over 1 minute, followed by 50 mL dextrose 50% i.v., with a further 300 mg if there is no response. Dicobalt edetate is potentially very toxic when administered to patients who do not have cyanide poisoning.
2. Patients with mild-moderate features should be given sodium thiosulphate 12.5 g i.v. over 10 minutes.
3. An alternative for moderate poisoning is hydroxocobalamin i.v. 5 g in adults given over 15 minutes. This can also be considered in patients with smoke inhalation where cyanide exposure is suspected clinically (as it has less risk of toxicity than other antidotes).
4. Patients with a metabolic acidosis should be given sodium bicarbonate.

DIGOXIN

CLINICAL FEATURES

Toxicity may result from ingestion of greater than 2–3 mg, or more commonly from taking too high a

daily dose and/or a reduction in renal elimination. Any cardiac arrhythmia may occur and adverse effects may be delayed for some hours. Severe poisoning can produce hyperkalaemia and hypotension.

TREATMENT

AC should be considered up to 1 hour post ingestion and multiple-dose charcoal may be effective by interrupting enterohepatic recirculation of the drug. A digoxin serum level may be helpful although it does not equate to the total body burden. Patients with hyperkalaemia should not be administered calcium gluconate (increased risk of cardiac toxicity); initial management is insulin–dextrose therapy. Those patients with persistent hyperkalaemia (>6.0–6.5), along with brady- or tachyarrhythmias associated with hypotension, should be treated with digoxin-specific antibody fragments.[19] Other treatments, particularly where digoxin-specific antibody fragments are not available, may be indicated but expert advice should be sought in these situations.

GAMMA HYDROXYBUTYRIC ACID (GHB) AND GAMMA BUTYROLACTONE (GBL)

CLINICAL FEATURES

In moderate to high ingestion, coma, convulsions, bradycardia, hypotension and severe respiratory depression can be seen, and other CNS depressant drugs potentiate the effects. Most patients who present to hospital merely require supportive care, and even those who present in coma are often awake within 2–4 hours; very few require intensive care.[20]

TREATMENT

Management is largely supportive; intubation is often not indicated even in those with significantly reduced levels of consciousness as airways reflexes tend to be maintained.[20] CT scanning should be considered in those with evidence of head injury, focal neurological signs or failure to wake after 1–2 hours. It is important before discharging a patient to determine whether they are potentially dependent users (daily use) and therefore at risk of withdrawal – expert advice on the management of these patients should be sought.

IRON

CLINICAL FEATURES

Iron poisoning classically has four phases:

- *phase 1:* initial GI symptoms secondary to direct corrosive action on gastric mucosa
- *phase 2:* latent asymptomatic phase
- *phase 3:* systemic iron toxicity
- *phase 4:* GI strictures several weeks after initial ingestion due to the initial direct GI corrosive effects.

The duration of phases 1 and 2 is dependent on the dose of iron ingested; some patients in very large ingestions may progress straight to a combined phase 1/3 presentation. Serum iron concentration is helpful in patient management.

TREATMENT

In those patients who present with features of severe iron poisoning, deferoxamine should be commenced at an initial rate of 15 mg/kg/h. The maximum licensed dose is 80 mg/kg/day; however, these patients may require more prolonged treatment and appropriate advice should be sought. For those presenting within 6 hours without severe symptoms, the management can be guided by a serum iron concentration 4–6 hours after ingestion (<55 μmol/L does not require treatment, >90 μmol/L treatment is recommended, 55–90 μmol/L treatment may be required depending on whether the concentration is not falling and/or the clinical condition of the patient). For those presenting more than 6 hours after presentation without severe features, the serum iron concentration is not as helpful in determining the need for treatment; expert advice should be sought for these patients.

ISONIAZID

CLINICAL FEATURES

Severe toxicity is characterised by coma, respiratory depression, hypotension and convulsions resistant to conventional treatments, and may result from doses >80 mg/kg. Protracted convulsions can cause rhabdomyolysis and acute renal failure.

TREATMENT

AC should be considered for large ingestions seen within 1 hour. Management of convulsions is initially benzodiazepines (i.v. 10–20 mg diazepam, or i.v. 4 mg lorazepam); those who fail to respond should be treated with 1 g of pyridoxine per gram of isoniazid ingested to a maximum of 5 g. Phenytoin should not be administered as it is ineffective and isoniazid inhibits the metabolism of phenytoin.

LITHIUM

CLINICAL FEATURES

There are two types of overdose: acute in lithium in naïve individuals/those on treatment, and chronic in those on long-term lithium treatment. For the latter this may be secondary to an intentional overdose or due to other factors such as dehydration or use of interacting drugs (e.g. NSAIDs, ACE-inhibitors, thiazide diuretics). Symptoms of toxicity can be divided as follows:

- *mild:* nausea, vomiting, fine tremor, polyuria, weakness

- *moderate:* confusion, urinary and faecal incontinence, myoclonic twitches/jerks, hypernatraemia, hyperreflexia
- *severe:* coma, renal failure, convulsions, cardiac arrhythmias.

TREATMENT

Lithium concentrations should be measured on arrival in chronic cases and then repeated every 4–6 hours; for acute overdoses, lithium concentrations should be measured 6 hours after ingestion and then every 4–6 hours. Patients should be adequately rehydrated, which may help with any renal impairment. Whole bowel irrigation (see above) should be considered in those who have ingested a potentially toxic amount of lithium. Extracorporeal elimination should be considered in those who have either severe features of lithium toxicity, or a serum lithium concentration of >7.5 mmol/L in acute overdoses or >4 mmol/L in chronic-related toxicity.

METHANOL AND ETHYLENE GLYCOL

CLINICAL FEATURES

Methanol and ethylene glycol are relatively non-toxic themselves, but their ingestion is a medical emergency because of their metabolism (following a latent period of 12–18 hours) to formic acid and glycolic acid respectively. These toxic metabolites account for the metabolic acidosis, ocular toxicity, renal failure and mortality that are occasionally seen. Mild features include dizziness, drowsiness and abdominal pain. When treatment is delayed, metabolic acidosis develops with drowsiness, coma and convulsions. The osmolal gap initially is elevated but then falls as the methanol or ethylene glycol is metabolised; the anion gap increases as the toxic metabolites build up.

TREATMENT

AC does not adsorb either methanol or ethylene glycol. The metabolic acidosis should be treated with sodium bicarbonate and the serum electrolytes measured. Ethanol prevents formation of the toxic metabolites and previously has been the most established treatment; its dosing is complex and it requires 1–2-hourly blood ethanol measurement and adjustment of the treatment. Additionally, it can cause significant CNS depression, necessitating critical care admission. Fomepizole (4-methypyrazole) has now become the antidote of choice – it is a twice-daily weight-based infusion without the need for specific monitoring and is not associated with neurological depression.[21] The initial dose is 15 mg/kg over 30 minutes, followed by a twice-daily infusion of 10 mg/kg for the next four doses and then increased to 15 mg/kg per treatment dose until treatment is no longer required. Ongoing management after initial loading dose often requires the involvement of clinical/medical toxicology services to facilitate ethylene glycol/methanol concentration measurement and interpretation of the results. It is important to remember with both ethanol and fomepizole that, should extracorporeal treatment be required, not only will the toxic alcohol be removed, but so too will the antidote; modifications to treatment regimens will be required.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

CLINICAL FEATURES

NSAIDs are commonly ingested in overdose; symptoms tend to be mild and consist of gastrointestinal symptoms. GI haemorrhage is not commonly reported in acute overdose of NSAIDs (apart from secondary to Mallory–Weiss tears). Convulsions can occur, but are usually associated with mefenamic acid (up to 10–15% of patients). Large ingestions of NSAIDs can be associated with metabolic acidosis and/or renal impairment.[22] Patients who do not develop symptoms within 4 hours are unlikely to experience delayed toxicity.

TREATMENT

AC can be given for large ingestions that are seen within 1 hour of the overdose. Convulsions should be treated with a benzodiazepine. Although there is no indication for routine use, those patients with symptoms of GI irritation can be treated with a short course of oral proton pump inhibitor. Metabolic acidosis should be treated with sodium bicarbonate and other measures as indicated. Supportive care and appropriate investigation are required for patients with renal impairment.

OPIOIDS

CLINICAL FEATURES

Overdose is characterised by pinpoint pupils, drowsiness, shallow breathing and ultimately respiratory failure.

TREATMENT

AC may be effective for oral ingestions; otherwise treatment is supportive. Naloxone 100–200 microgram boluses should be given i.v. and increased as titrated to clinical response. In patients who fail to respond to 2 mg, alternative diagnoses should be considered. Those who respond may require repeat doses, particularly where a long-acting or sustained/modified release preparation has been ingested; an infusion of naloxone may be required in these patients. Intubation and mechanical ventilation are required if respiratory failure is not rapidly reversed by naloxone.

PARACETAMOL

There is increased metabolism of paracetamol to its toxic metabolite, *N*-acetyl-*p*-benzoquinonimine (NAPQI) as normal conjugation pathways are exceeded. This toxic metabolite irreversibly binds to hepatocytes leading to cell death and release of inflammatory and cytotoxic mediators and further hepatocyte death. There have been recent changes to the management of paracetamol management in the UK, which have not yet been finalised. The antidote for paracetamol poisoning is *N*-acetylcysteine. Although i.v. acetylcysteine administered more than 16 hours after ingestion may not prevent severe liver damage, it should still be given since outcome from paracetamol-induced fulminant hepatic failure is improved. Although severe hepatic injury has a 10% mortality, the majority of patients recover within 1–2 weeks.[23]

CLINICAL FEATURES

Paracetamol poisoning is often asymptomatic in early stages (first 24–48 hours); later presentations may be associated with evidence of acute liver injury/failure. Patients with very significant ingestions (initial 4-hour paracetamol concentrations of >800 mg/L) may present in coma with a lactic metabolic acidosis – this is a direct effect of the paracetamol.

TREATMENT

- Those patients who present within an hour – consider activated charcoal in significant ingestions.
- Current UK treatment guidelines for single known time point ingestions are based on a single treatment line starting at 100 mg/L at 4 hours post ingestion. Risk stratification is no longer required to determine the need for treatment.
- For those with staggered, supratherapeutic or unknown time of ingestions, treatment is not required for those who have ingested <75 mg/kg in the last 24 hours but is required for those who have ingested >150 mg/kg (these are based on actual body weight to a maximum of 110 kg). For those who have ingested between 75 and 150 mg/kg, advice should be sought on whether or not treatment is required.
- *N*-acetylcysteine 150 mg/kg in 200 mL 5% dextrose is infused over 1 hour, followed by 50 mg/kg in 500 mL 5% dextrose over 4 hours and 100 mg/kg in 1 L 5% dextrose over 16 hours (total dose 300 mg/kg in 20 hours). Maximum protective effect is time-dependent. An ingestion–treatment interval of less than 10 hours gives the best results.
- In those patients with evidence of liver injury, the last dose (100 mg/kg in 1 L 5% dextrose over 16 hours) is repeated until the patient's condition and biochemical and haematological results are improving.
- Although there is limited evidence, many recommend the use of prolonged *N*-acetylcysteine in patients with acute kidney injury.
- Expert opinion should be sought early on from a regional centre if liver failure is progressive since liver transplantation may become necessary.

PARAQUAT

In adult humans the lethal dose is 3–6 g (i.e. 15–30 mL of 20% w/v liquid concentrate). The mortality rate in patients ingesting the liquid concentrate is about 45%.[24] The lung is the primary target organ, with the injury being enhanced by oxygen. Peak concentrations are achieved between 0.5 and 2 hours.

CLINICAL FEATURES

Initial symptoms are gastrointestinal pain and vomiting with corrosive effects on the mouth, pharynx and oesophagus. Dyspnoea and pulmonary oedema follow within 24 hours, progressing to irreversible fibrosis and death. Cardiac, renal and hepatic dysfunctions are common.

TREATMENT

Those treating suspected paraquat-poisoned patients should wear appropriate personal protective equipment to prevent secondary exposure. An urgent qualitative urine test (dithionite spot test) should be undertaken to confirm exposure; a confirmatory plasma concentration should be measured in those where positive as this may guide prognosis. Management is largely supportive: analgesia for oropharyngeal burns and other measures as indicated by the patient's clinical condition. Oxygen therapy can increase the degree and severity of pulmonary fibrosis. Palliative care may be required in those with high paraquat concentrations who fail to respond to treatment. Expert advice should be sought in these patients, to determine whether other treatment options may be appropriate.

PHENYTOIN

CLINICAL FEATURES

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. After initial nausea and vomiting, neurological symptoms develop including drowsiness, dysarthria and ataxia, and may ultimately progress to seizures. Cardiovascular toxicity is rare unless the overdose has been given i.v.

TREATMENT

Most patients require nothing more than supportive measures. There is some evidence from volunteer studies that multi-dose activated charcoal can increase the elimination of phenytoin; it is not clear whether this alters the outcome.

SALICYLATES (ASPIRIN)

Moderate toxicity occurs with serum concentrations 500–750 mg/L (3600–5500 μmol/L) and severe

toxicity with concentrations >750 mg/L. Serum concentrations alone do not determine prognosis. The elimination half-life increases significantly with increasing concentrations. Small reductions in pH produce large increases in non-ionised salicylate, which then penetrates tissues.

CLINICAL FEATURES

Tinnitus, deafness, diaphoresis, pyrexia, hypoglycaemia, haematemesis, hyperventilation and hypokalaemia may all occur. Coma, hyperpyrexia, pulmonary oedema and acidaemia are reported as more common in fatal cases, which present late.

TREATMENT

Although multiple-dose AC is not recommended by some experts, most medical toxicologists would recommend its use in large ingestions since concretions of salicylates in the stomach can occur with delayed ongoing absorption. Urinary alkalinisation (see above) decreases the amount of non-ionised drug available to enter tissues and should be considered in those with moderate/severe toxicity. Extracorporeal techniques are very effective in removing salicylates and correcting acid–base disturbance.[25]

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIS) OR 5-HT DRUGS

SSRIs include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline. These drugs have increasingly replaced the tricyclic antidepressants and generally appear to be much safer in overdose.

CLINICAL FEATURES

Drowsiness, tachycardia and mild hypertension are the commonest features. Seizures and coma can occur, as well as a serotonin syndrome in 14% of cases.[26]

TREATMENT

AC should be considered up to 1 hour post ingestion, otherwise treatment is supportive. Benzodiazepines should be used to treat agitated or hyperthermic patients. There are case reports of cyproheptadine being used to treat severe toxicity with SSRIs.[27] In those with hyperthermia, the advice as above for amfetamines should be followed in terms of assessment of the hyperthermia and appropriate management interventions.

THEOPHYLLINE

CLINICAL FEATURES

Acute theophylline poisoning is potentially very serious and severe poisoning carries a high mortality. Toxic effects such as agitation, tremor, nausea, vomiting and sinus tachycardia become evident at <30 mg/L (167 μmol/L). Concentrations >60 mg/L (333 μmol/L) in acute poisoning or >40 mg/L (222 μmol/L) in chronic usage frequently result in seizures, malignant ventricular arrhythmias, severe hypotension and death.[28] A key feature is hypokalaemia, which predisposes to arrhythmias and rhabdomyolysis. Measuring plasma theophylline levels confirms the ingestion and may help in deciding elimination methods; in the majority of poisoned patients they do not aid management. Sustained-release preparations may result in delayed onset and prolonged toxicity.

TREATMENT

Multi-dose AC should be considered, particularly in those with serum concentrations of greater than 40 mg/L. Although hypokalaemia does occur, there is not a total body depletion of potassium; therefore only potassium concentrations of less than 3 mmol/L should be cautiously replaced; monitor for a rebound hyperkalaemia. Convulsions should be treated with benzodiazepines and cardiac arrhythmias with beta blockers in non-asthmatic patients. Vomiting is often severe, and requires appropriate antiemetic administration.

TRICYCLIC ANTIDEPRESSANTS (TCAs)

CLINICAL FEATURES

These drugs remain the leading cause of death from overdose in patients arriving at the emergency department alive and account for up to one-half of all overdose-related adult intensive care admissions.[29] Features include anticholinergic effects such as warm dry skin, tachycardia, blurred vision, dilated pupils and urinary retention. Severe features include respiratory depression, reduced conscious level, cardiac arrhythmias, fits and hypotension. Arrhythmias may be predicted by a QRS duration >100 ms on the ECG; a QRS duration of >160 ms increases risk of seizures. All forms of rhythm and conduction disturbance have been described, and are not necessarily predicted by the ECG.[30] Amoxapine typically causes features of severe poisoning in the absence of QRS widening. Cardiac toxicity is due mainly to quinidine-like actions, slowing phase 0 depolarisation of the action potential. Other mechanisms include impaired automaticity, cholinergic blockade and inhibition of neuronal catecholamine uptake. Toxicity is worsened by acidaemia, hypotension and hyperthermia.

TREATMENT

After supportive care as outlined above, including multiple-dose AC, continuous cardiac monitoring is essential. Increasing arterial pH to ≥7.45 significantly reduces the available free drug and this may be the best way to avoid TCA toxicity. Mild hyperventilation and 8.4% sodium bicarbonate in 50 mmol aliquots achieves this strategy and may improve outcome.[31] Bicarbonate

should probably be given in all cases of QRS prolongation (even in the absence of metabolic acidosis), arrhythmias with associated hypotension or metabolic acidosis; it should also be considered in those with convulsions. If arrhythmias occur, avoid class 1a agents; lidocaine may be best. Benzodiazepines are the drug of choice for sedation, treatment of seizures and may prevent emergence delirium.

VALPROATE

CLINICAL FEATURES

Most overdoses follow a benign course, with nausea, mild drowsiness and confusion. Coma can occur in large ingestions with cerebral oedema. There is the potential for metabolic derangement, including metabolic acidosis, hypernatraemia, hypoglycaemia and hyperammonaemia.

TREATMENT

Valproate levels are of little value, except to confirm the ingestion. There is poor correlation between depth of coma and free or total valproate levels. Supportive management is all that is usually required. Although in therapeutic use valproate is extensively protein-bound, with increasing plasma concentrations there is saturation of this binding leading to increased free drug; in these situations consider haemodialysis. Additionally, in those patients with significant overdoses and associated hepatic dysfunction and hyperammonaemia, consider the use of L-carnitine.

Sedation and pain management in intensive care

Luke E Torre

Despite the widespread use of sedative and analgesic agents in the intensive care unit (ICU), the goals of sedation and analgesia are not well established.[1] Having its roots in anaesthesia, ICUs would historically manage patients with full general anaesthesia including skeletal muscle paralysis and controlled ventilation modes and this was maintained until the disease process remitted. Sedation and analgesia were considered a necessary adjunct to the management of critically ill patients.

Combinations of opioids and benzodiazepines are commonly used to provide 'sedation' in the ICU. As high doses of opioids analgesics may result in significant sedation in their own right and are synergistic with sedative agents, the distinction between sedation and analgesia is blurred. This makes the definition and attainment of clear sedation goals elusive.

SEDATION

There has been a paradigm shift in thinking towards sedation practice in ICUs over the past 30 years. A combination of factors have led to this change, notably:

- improved ventilator technology and modes of ventilation allowing synchronised and spontaneous respiration
- improved drug development for sedation and analgesia with pharmacokinetic profiles that allow prompt titration, and pharmacodynamic profiles with fewer side-effects
- the development and implementation of sedation scoring systems in the ICU[2]
- the increasing use of percutaneous tracheostomy and/or non-invasive ventilation (NIV) for patients requiring prolonged ventilation
- the recognition of critical illness polyneuropathy and myopathy and the risk factors associated with it
- the separation and specialisation of intensive care physicians from other domains
- the emerging high-quality evidence in the field of sedation and analgesia in intensive care
- economic pressures and increased demand for finite intensive care resources.

Today, sedative use in the critically ill should be for one or more of the following purposes:

- a treatment for disease processes such as: seizures, raised intracranial pressure, serotonin syndrome and alcohol withdrawal
- to facilitate tolerance of intensive care therapies such as intubation, mechanical ventilation and active cooling
- to reduce oxygen consumption by reducing patient arousal, activity and anxiety
- to maintain the safety of patient and carers when dealing with the hyperactive delirious patient
- palliation
- procedural sedation.

Sedation of patients in the ICU is an integral part of what health care workers perceive to be care and compassion for the critically ill patient. Presumed benefits of sedative agents include:

- reducing patient anxiety over their illness, the welfare of relatives or the risk of death
- providing adequate rest
- reducing the distress of unpleasant sensations, invasive treatments and monitoring
- blunting awareness of the environment over which the patient has very little control and in which he/she may be unable to communicate.

Non-pharmacological methods should preferentially be used to help manage these issues. Avoiding potentially distressing situations, allowing adequate access to caring visitors, maintenance of good communication with the patient and a positive outlook by carers will satisfy many of these goals. Small comforts, such as ice chips by mouth, a comfortable mattress, relaxation music and maintaining a daytime/night-time environment all help this process.

LEVEL AND ASSESSMENT OF SEDATION

Critical to delivery of sedation is an accurate sedation assessment tool. Sedation scoring systems were first introduced in the 1970s.[2] Since that time, several validated scoring systems for critically ill patients have become available. The Ramsay Sedation Scale (RSS) and Richmond Agitation Sedation Scale are two of the most popular used worldwide (**Tables 89.1** and **89.2**). Despite their availability, validation and evidence base, their

Table 89.1 Ramsay Sedation Scale

LEVEL	RESPONSE
AWAKE LEVELS	
1	Patient anxious and agitated or restless or both
2	Patient cooperative, orientated and tranquil
3	Patient responds to commands only
ASLEEP LEVELS	
4	Brisk response to a light glabellar tap or loud auditory stimulus
5	Sluggish response to a light glabellar tap or loud auditory stimulus
6	No response to a light glabellar tap or loud auditory stimulus

Table 89.2 The Richmond Agitation Sedation Scale[56]

POINT	PATIENT RESPONSE TO VERBAL AND PHYSICAL STIMULI
+4	Combative – combative, violent, immediate danger to staff
+3	Very agitated – pulls or removes tubes or catheters; aggressive
+2	Agitated – frequent non-purposeful movement, fights ventilator
+1	Restless – anxious, apprehensive but movements not aggressive or vigorous
0	Alert and calm
–1	Drowsy – not fully alert, but has sustained (>10 seconds) awakening (eye opening/ contact) to voice
–2	Light sedation – drowsy, briefly (<10 seconds) awakens to voice or physical stimulation
–3	Moderate sedation – movement or eye opening (but not eye contact) to voice
–4	Deep sedation – no response to voice, but movement or eye opening to physical stimulation
–5	Unarousable – no response to voice or physical stimulation

incorporation into routine management of intensive care patients remains low.[3]

Electroencephalography (EEG), which may be either ‘raw’ or ‘processed’, is able to provide a measure of cerebral activity. This monitor is more suitable for assessing depth of anaesthesia and may be difficult to interpret in the encephalopathic patient. Newer, easy to use devices using integrated EEG (e.g. Bi-spectral Index (BIS)) are now available. Evidence of their efficacy is appearing, but their role in the ICU is not well established.[4] Their use is also limited by practical considerations, such as interference due to movement artefact. To date these monitors have not enjoyed widespread use in the ICU, but may be useful for specific indications such as ensuring an isoelectric EEG in patients being treated for very high intracranial pressure.

SEDATION STRATEGIES

Although the choice of sedative agent(s) must be a conscientious decision based on pharmacokinetic and pharmacodynamic factors relevant to the critically ill patient, it is perhaps of greater importance to decide on the sedation strategy employed.

A variety of strategies have been described, some more novel than others:

- goal-directed sedation
- patient-targeted sedation protocols
- daily interruption of sedation
- intermittent sedation
- ‘analgosedation’ or analgesia-based sedation
- patient-controlled sedation.

The purpose of these strategies should be to achieve a controlled and predetermined level of sedation in the patient. The chosen level of sedation will be intimately linked to the underlying disease process, patients’ characteristics and the treatments and interventions they are receiving. The aim of sedation should be documented by the team and conveyed to the bedside nurse, who will have the largest impact on achieving and maintaining the chosen level. Once instituted, the level of sedation should be regularly assessed.

Goal-directed sedation was the first method described where sedatives are freely adjusted (usually by the bedside nurse) to attain a prescribed level of sedation from a sedation scoring system.[2]

Patient-targeted sedation protocols implement two main features: a structured approach to the assessment of patient pain and distress, coupled with an algorithm that directs drug escalation and de-escalation based on the assessments.[5]

Daily interruption of sedation: this strategy employs a similar goal of sedative and analgesic titration to a desired depth of sedation. In contrast to ‘patient-targeted sedation protocols’, no formal algorithm has been established for drug escalation. However, the risk of excessive sedation is minimised by a daily interruption of both sedative and analgesic infusions until the patient awakens or exhibits distress that mandates resumed drug administration, usually with an initial bolus followed by a reduced infusion rate.[5]

Intermittent sedation administration involves use of longer-acting sedative agents, typically lorazepam, given by intermittent bolus titrated via a sedation scoring system.

'*Analgosedation*' is a more modern approach gaining favour in selected patients where sedation is not required as a treatment of their disease process. In these patients, opioid analgesia is instituted first, and once pain is adequately controlled, verbal measures are used to calm the patient to a targeted sedation level (e.g. Ramsay score 3–4). Major tranquillisers (e.g. haloperidol) are given for delirium and only then are sedative agents (e.g. propofol) used for short-term infusion and promptly ceased.[6]

Proposed benefits of the above sedation strategies include:[5–9]

- shorter duration of mechanical ventilation
- shorter length of ICU and hospital stay
- economic benefit
- less need for diagnostic studies (e.g. computed axial tomography (CT) scans) to assess impaired conscious state
- less ventilator-associated pneumonia
- a possible mortality benefit.

Criticisms of these strategies include:

- high self-extubation rates
- promotion of myocardial ischaemia
- triggering of a withdrawal syndrome.

Concerns over increased long-term neuropsychological effects (e.g. post-traumatic stress disorder) have been unfounded. Instead, evidence suggests a reduced incidence of these complications using such strategies.[10,11]

SEDATIVE AGENTS

GABA-A RECEPTOR AGONISTS

Gamma amino butyric acid (GABA) is a major neurotransmitter in the central nervous system, and one that is involved in the complex process of sedation. It binds to the alpha subunit of the GABA-A receptor and, by activation, causes a conformational change that opens the ligand-gated channel, allowing chloride ion influx into the neuron. This hyperpolarises the neuronal membrane and reduces neuronal activity leading to sedation.[12]

The GABA-A receptor agonists used in intensive care are benzodiazepines, propofol and barbiturates. They all share amnesic, hypnotic, anxiolytic and anticonvulsant effects, but have no analgesic properties.

Benzodiazepines

Benzodiazepines (BZAs), as a class, are probably the most widely used sedatives in ICUs. BZAs are good anticonvulsant drugs and also provide some muscle relaxation. They bind to the gamma subunit of the GABA-A receptor, resulting in a conformational change causing increased opening frequency of the channel.[13] The commonest agents used worldwide are midazolam, lorazepam and diazepam.

These drugs may be given by many routes, but most commonly intravenously (i.v.) or orally (p.o.) in critically ill patients. Intravenous administration is by either continuous or intermittent i.v. infusion (e.g. midazolam in 1 mg/mL dilution, titrated to effect).

Dosage of these agents may vary widely depending on various pharmacokinetic and pharmacodynamic factors such as:

- prior exposure to BZA (increased tolerance)
- age and physiological reserve
- volume status (hypovolaemic patients are more sensitive)
- renal and hepatic dysfunction
- co-administered drugs (e.g. combined with an opioid)
- history of alcohol consumption (increased tolerance).

Although some BZAs (e.g. midazolam) are short-acting, water-soluble agents, there is potential for accumulation of both parent compound and active metabolites in patients with hepatic and/or renal dysfunction. This is especially pertinent in the critically ill, where there may be extensive derangement of BZA pharmacokinetic profiles.[14,15] This may result in prolonged sedation and increased length of mechanical ventilation and ICU stay. There is, therefore, some difficulty in predetermining suitable dosages of these agents. Midazolam, in doses of 0.02–0.2 mg/kg/h may be suitable, with the level titrated to individual response. Longer-acting agents, such as diazepam, may be given by intermittent i.v. injection (e.g. diazepam 5–10 mg) as necessary.

BZAs are often combined with opioids in a compound 'sedative' infusion. This allows lower doses of BZA to be used, while capitalising on the opioid effects of respiratory and cough suppression, to facilitate mechanical ventilation and tube tolerance.

Flumazenil (flumazepil), the specific BZA antagonist, may be used to reverse the effect of BZAs to reduce unwanted acute side-effects, such as severe hypotension or respiratory depression, or to allow acute neurological assessment of the sedated patient.

Propofol

The i.v. anaesthetic agent propofol (2,6-di-isopropylphenol) is frequently used for sedation in the ICU. It binds to the beta subunit on the receptor and causes a conformational change to the chloride channel.[13] It gives more profound hypnosis than BZAs, which have a ceiling effect. It is given by continuous i.v. infusion.

It has a favourable pharmacokinetic profile compared with BZAs due to rapid hepatic and extrahepatic conjugation reactions to inactive metabolites. Indeed, clearance of propofol exceeds hepatic blood flow. This gives it a relatively short context-sensitive half-time, resulting in rapid offset, particularly after prolonged infusion.

Although propofol has been shown to reduce time on mechanical ventilation compared with BZA (specifically midazolam) sedation, it has not been shown to reduce time in the ICU.[16,17] Its combination with remifentanil, however, may result in a shorter ICU length of stay compared with the combination of midazolam with either fentanyl or morphine.[18,19]

Caution is required in hypovolaemic patients or those with impaired myocardial function as severe hypotension may result.[20] Doses for ICU sedation are generally much lower than those required for anaesthesia. The diluent in which propofol is delivered is lipid-rich and may have to be taken into account as a source of nutrition and indeed cause of hyperlipidaemia, depending on dosage and duration of therapy. Disodium edetate, present in the propofol solution, does not appear to be harmful in patients receiving long-term infusions of propofol.[21]

There continues to be concern about 'propofol infusion syndrome' particularly in paediatric patients who have developed severe heart failure (preceded by metabolic acidaemia, fatty infiltration of the liver and striated muscle damage) after prolonged, high-dose infusions of propofol.[22] The pathophysiology of this condition remains elusive but may relate to uncoupling of oxidative phosphorylation in mitochondria. There may also be a genetic susceptibility.[23] Caution should therefore be exercised when using propofol for prolonged periods and infusion rates should be limited to 4 mg/kg/h. Hyperlipidaemia may be a warning sign for development of the syndrome and serum triglyceride monitoring should be considered in patients at risk.[24] Management requires immediate cessation of propofol and cardiovascular supports, which may necessitate ECMO.[25] The condition, although rare, has a high mortality.

Barbiturates

Thiopentone is reserved for specific indications, such as management of intractable intracranial hypertension, or for the treatment of status epilepticus. It is not commonly used as a general sedative agent due to a long context-sensitive half-time when given by continuous infusion.

VOLATILE ANAESTHETIC AGENTS

The use of volatile anaesthetic agents for sedation in the ICU has been limited by:

- the cost of prolonged administration
- the more complex set-up required for the administration of these agents (vaporiser, scavenging apparatus, etc.)
- specific side-effects such as; 'halothane' hepatitis; accumulation of fluoride ions and consequent renal dysfunction (sevoflurane (fluoromethyl hexafluoroisopropyl ether) and isoflurane), compound A accumulation and possible renal dysfunction (sevoflurane and absorbent interaction)
- occupational health and safety concerns (e.g. spontaneous miscarriage).

Isoflurane and sevoflurane provide hypnosis, amnesia and, at higher concentrations, immobility of the patient. They have no analgesic properties. Their mechanism of action remains hotly debated. Desflurane, due to its low boiling point, has not yet been successfully incorporated into intensive care ventilator systems.

Volatile agents are useful for short periods of anaesthesia during invasive procedures in the ICU. They have classically been used for longer periods of sedation in acute severe asthma, due to their bronchodilator effect.

Newer vaporiser systems, such as the AnaConDa® (Anaesthetic Conserving Device), allow safe administration and recirculation of volatile agent through a standard ICU ventilator. Approximately 90% of the volatile agent is recirculated, greatly reducing cost.[26]

Studies generally show reduced time to awakening and extubation with short-term volatile administration compared with BZAs. Although fluoride levels are higher in patients receiving volatile agents, no significant adverse renal events have been attributed to it.[26] A recent study in ICU patients receiving prolonged sedation showed that sevoflurane reduced time to extubation and post-extubation opioid requirements compared with GABA-A agonists.[27] Other potential advantages include:

- lack of a withdrawal syndrome
- predictable offset independent of renal or hepatic dysfunction
- cardioprotective effects
- no tachyphylaxis
- lower incidence of delirium
- ability to measure and titrate end-tidal volatile concentration.

NMDA RECEPTOR ANTAGONIST

Ketamine acts by blocking NMDA receptors. It produces a sedative state known as 'dissociative anaesthesia', with the following characteristics:

- mild sedation
- amnesia
- analgesia
- reduced motor activity.

The lack of respiratory and cardiovascular depression at lower doses makes this a relatively safe drug for use in the ICU. Limitations to its use include hallucinations, and delirium during the recovery/withdrawal phase. These may be ameliorated by BZA administration. Ketamine may be used specifically for sedation in severe asthmatics (for its bronchodilator effect), in patients following head injury (for its effect at the NMDA receptor) or in patients where analgesia is difficult (e.g. extensive burns).[28,29]

MAJOR TRANQUILLISERS

Butyrophenones (e.g. haloperidol) and phenothiazines (e.g. chlorpromazine) are very useful agents for the sedation of delirious patients in the ICU. They act via a range of receptors including dopaminergic (D1 and D2), alpha-adrenergic, histamine, serotonin and cholinergic receptors. Main actions include:

- reduced motor activity
- apathy and reduced initiative
- sedation and drowsiness
- reduced aggression
- antiemetic.

Unwanted effects with these drugs are common and include:

- extrapyramidal effects (dystonia, akathisia and parkinsonism)
- endocrine effects (e.g. lactation)
- anticholinergic effects (e.g. blurred vision, dry mouth, urinary retention, constipation)
- hypotension
- neuroleptic malignant syndrome.

The advantage of major tranquillisers is that they can be used to gain control in difficult situations (e.g. when delirious patients may be a risk to themselves or their carers), without major risk of respiratory depression. They should not be used for long-term sedation, except for the specific treatment of psychosis. Typically haloperidol, diluted to a 1 mg/mL solution, may be given by repeated i.v. injection in doses of 2–20 mg/h until the delirious patient is approachable. Repeat dosages would then be titrated to allow easy arousal of the patient. Haloperidol may also be given p.o. or by i.m. injection. Recent interest has emerged with haloperidol use in elderly surgical patients in intensive care as prophylaxis against delirium.[30]

Atypical antipsychotic agents, such as olanzapine and quetiapine, are also efficacious agents for the management of delirious patients.[31] They have a lower side-effect profile than the 'typical' antipsychotics, especially with respect to extrapyramidal side-effects. They are usually given orally, although olanzapine may be given as sublingual wafers, a particularly useful route of administration in these patients.

α_2-AGONISTS

Dexmedetomidine is a highly selective α_2-agonist with a half-life of 2 hours. It provides safe analgesia and sedation in the ICU when given as a single agent by i.v. infusion.[32–35] Although originally licensed in Australia for 24-hour use, longer-duration infusions have been safely administered.[36,37] Compared with benzodiazepines, dexmedetomidine results in less delirium and shorter time to extubation.[38] This may impact on ICU length of stay and provide a significant cost benefit. Furthermore dexmedetomidine is showing promise as an effective treatment of agitated delirium in critically ill patients.[39]

Dexmedetomidine aims to deliver a cooperative, calm and tube-tolerant patient, without respiratory depression.[33] Extubation is usually performed with the agent still infusing to maintain the tranquil cooperative state. Opioid analgesic requirements are less compared with GABA agonist sedation.[36]

A loading dose of 1 μg/kg over 10 minutes is recommended in healthy patients, but this should be avoided or attenuated in the critically ill. Infusion rates of 0.2–1.0 μg/kg/h are recommended. Higher rates have been reported, but bradycardia is more frequently seen.[32,37,40] Side-effects may be predicted from the mechanism of action and include hypotension and bradycardia.

Clonidine, an established long-acting α_2-agonist, may be used to enhance sedation and analgesia when GABA-A agonists and opioids are used as the mainstay of sedation in the ICU. The usual i.v. dose range is 50–150 μg, 4–6 hourly.

ANALGESIA

Pain management is a priority in the care of critically ill patients. Skilled use of analgesics in the modern ICU aims to ensure that critically ill patients no longer suffer pain. Pain management relies largely on the use of opioid analgesics together with regional anaesthetic techniques and other adjuncts.

Many patients present to the ICU with painful conditions or undergo painful procedures during their stay. Patients commonly report pain from routine ICU procedures like arterial and central venous cannulation, endotracheal suctioning, insertion of an indwelling urinary catheter or nasogastric tubes and even turning in bed.[41] In addition, other adverse symptoms commonly reported include: unsatisfied thirst, difficult sleeping, anxiety, unsatisfied hunger, depression and shortness of breath.[41]

Pain has a number of adverse consequences, such as:

- provoking anxiety
- contributing to lack of sleep
- worsening delirium
- increasing the stress response
- causing respiratory embarrassment due to atelectasis and sputum retention
- causing immobility with venous and gut stasis.

Pain management comprises a number of modalities in addition to pharmacological methods, including:

- a caring and supportive ICU team, whom the patient can trust
- warm and comfortable surroundings
- attention to pressure areas
- bowel and bladder care
- adequate hydration and amelioration of thirst (e.g. moistening the mouth)

- early tracheostomy where indicated to reduce the discomfort of endotracheal intubation
- supplemental treatments such as acupuncture, acupressure, massage and transcutaneous electrical nerve stimulation (TENS).

OPIOIDS

Opioids remain the mainstay of analgesia in the ICU. The most commonly used agents in the ICU used worldwide include:

- morphine and its analogues (e.g. diamorphine, codeine)
- semisynthetic and synthetic agents:
  - phenylpiperidine derivatives (e.g. pethidine, fentanyl, sufentanil, remifentanil)
  - methadone
  - thebaine derivatives (e.g. buprenorphine, oxycodone).

The effects of opioids are mediated via the four opioid receptor subtypes; mu, kappa, delta and nociceptin/orphanin FQ. These are G-protein-coupled receptors that inhibit adenyl cyclase to reduce cAMP. This results in analgesia mediated at supraspinal, spinal and peripheral nerve endings.[42] The side-effects of opioids are well described.

Opioids are titrated to effect by intermittent i.v. injection, or by continuous infusion. This may be controlled by the nurse (nurse-controlled analgesia or NCA) or by the patient (patient-controlled analgesia or PCA). Suitable regimens are 1 mg/mL of morphine, or 20 µg/mL of fentanyl titrated to effect.

NCA is often combined with a BZA such as midazolam to produce a 'sedative/analgesic' infusion for patients on mechanical ventilation (see sedation section). Opioids can also be administered via the subarachnoid, epidural, transdermal, oral, sublingual and intranasal routes.

The effect of analgesia in the clinical setting is judged by:

- patient response, if they are conscious, either verbally by describing the level of pain subjectively or by using a visual analogue score (**Fig. 89.1**) or other assessment, such as behavioural pain scales[43,44]
- physiological markers of distress (e.g. tachycardia, hypertension, diaphoresis, restlessness).

These indicators should be assessed in the clinical context – that is, to what degree is the pathophysiological process contributing to pain? In the critically ill, the use of opioids may be complicated by:

- wide inter-individual response to similar dosages, especially in debilitated and elderly patients. Partial opioid agonists (such as buprenorphine) may be advantageous in these scenarios. They may be administered transdermally or sublingually
- severe hypotension following rapid administration, particularly in hypovolaemic patients

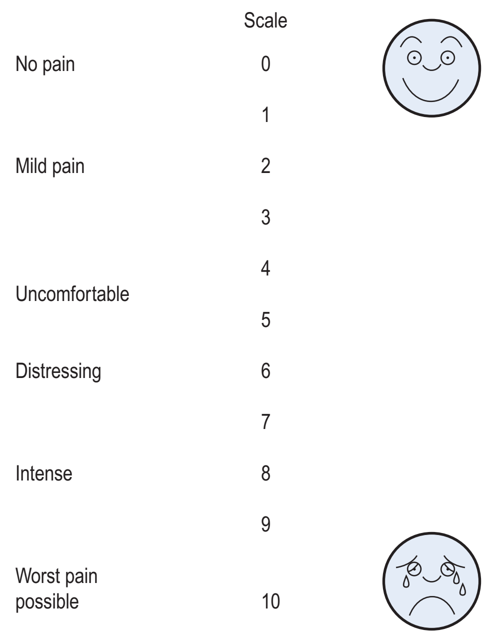

Figure 89.1 Visual analogue score for the assessment of pain.

- prolonged duration of action, due to accumulation of parent compound and metabolites (e.g. morphine and its major metabolites morphine-3-glucuronide and morphine-6-glucuronide) in the elderly and in patients with renal and hepatic dysfunction. Use of drugs with shorter half-lives (e.g. fentanyl or sufentanil) or those with organ-independent metabolism (e.g. remifentanil) can reduce this problem
- constipation, often requiring concomitant administration of aperients to promote regular evacuation and prokinetics to prevent gastrostasis and allow enteral feeding
- the development of tolerance
- withdrawal symptoms on cessation or reduction of opioid medication.

Recognition of withdrawal symptoms is not always simple in ICU patients as they may mimic sepsis or delirium. Treatment is by reinstitution of and then slow withdrawal of the opioid. Alternatively, symptoms may be controlled by substitution for a long-acting opioid (e.g. methadone), BZAs or α_2-agonists.

The specific opioid antagonist naloxone has little role to play in the ICU, except for the treatment of severe hypotension, unwanted sedation or respiratory depression following opioid usage or overdose. Rapid reversal of opioid effect for the purpose of neurological assessment may be another valid use.

REMIFENTANIL

This is a synthetic, selective mu receptor agonist. It undergoes organ-independent hydrolysis by plasma,

red blood cell and tissue esterases. It has a reliable context-sensitive half-time of 4 minutes, which makes it particularly attractive for critically ill patients.

Although an analgesic, it is gaining favour as a sedative agent in intensive care as it causes sedation, tube tolerance and a slowed respiratory rate. In addition, its pharmacokinetic profile makes it ideal for rapid neurological assessment. Studies show reduced extubation times and ICU length of stay when compared with traditional opioids.[18,19]

The loading dose is usually 1 μg/kg, however this should be avoided or attenuated in critically ill patients. Continuous infusion rates of 0.05–0.5 μg/kg/min are usually required and a starting rate of 0.1 μg/kg/min is recommended. Dosage alterations are usually in increments of 0.025–0.1 μg/kg/min. Due to the short half-life, adequacy of response can be assessed within 20 minutes.

Weaning should also be done by incremental dose reductions due to the risks of rebound hyperalgesia. Adding ketamine during the weaning process may modulate this risk.[45]

SIMPLE ANALGESICS

Paracetamol and other simple analgesics (e.g. salicylates) are particularly effective for:

- musculoskeletal pain
- perioperative pain
- inflammatory conditions
- multimodal analgesia, to reduce opioid requirements.

These drugs are given p.o., per rectum (p.r.) or i.v. to supplement analgesia in the critically ill (e.g. paracetamol 1–2 g 4–6-hourly). Paracetamol use is limited by the risk of hepatic dysfunction if used in high dose or for prolonged periods.

NSAIDs

The commonly used NSAIDs are carboxylic acids (e.g. indometacin (indomethacin), ibuprofen, mefenamic acid) or enolic acids (e.g. piroxicam). NSAIDs are useful for supplemental/multimodal analgesia in the ICU for the conditions listed for simple analgesics above. They are given p.o., p.r. or by intramuscular (i.m.) injection (e.g. indometacin 100 mg twice daily p.r.). Patient selection is paramount in the critically ill due to their serious side-effects, including:

- renal dysfunction
- gastrointestinal haemorrhage
- increased bleeding tendency due to platelet inhibition.

The newer cyclo-oxygenase-2 specific inhibitors (COX-2), such as valdecoxib and its injectable precursor parecoxib, have a much lower side-effect profile than traditional NSAIDs. This group of drugs should be used for only short periods, due to an increased cardiovascular morbidity associated with long-term use.[46] COX-2 inhibitors should be avoided in postoperative cardiac surgical patients due to an increased incidence of thromboembolic complications and sternal wound infection.[47,48]

TRAMADOL

Tramadol is a synthetic, racemic preparation with multiple analgesic actions. The (+) enantiomer is a mu receptor agonist and serotonin reuptake inhibitor, whereas the (−) enantiomer is a norepinephrine reuptake inhibitor.[49] In addition to mu receptor action, which accounts for approximately 30% of its analgesic effect, it also enhances the descending inhibitory pathways involved in pain modulation.[50] It is useful for moderate to severe pain in the postoperative patient in doses of 50–100 mg i.v., p.o. or i.m. 4-hourly to a maximum of 600 mg/day. Patients are at risk of developing serotonin syndrome whilst taking tramadol in combination with other pro-serotonergic agents.[51]

KETAMINE

(See 'NMDA receptor antagonist' above.) Ketamine is commonly used as part of multimodal analgesic regimens in surgical patients with severe pain, or if tolerant to opioids. Continuous infusion in a dosage range of 0.1–0.2 mg/kg/h is recommended.

NITROUS OXIDE

Short-term administration of Entonox (50% nitrous oxide in oxygen) is still useful for analgesia during painful procedures (e.g. burns dressings). This may be given by demand valve (controlled by the patient) or be administered by the medical staff.

LOCAL ANAESTHETICS – REGIONAL ANALGESIA

The use of local anaesthetic techniques in the critically ill patient is limited by:

- pain often emanating from multiple sources and therefore not amenable to a single regional technique
- the requirement for i.v. sedation/analgesia (for reasons previously outlined), making a regional technique for a source of pain superfluous
- the need to treat pain over a prolonged period, mandating either repetition of the regional block or the placement of an indwelling catheter (e.g. epidural catheter). Indwelling catheters have a defined duration of insertion (usually 3–4 days) before needing to be removed due to increasing infection risk

- coagulopathy and thrombocytopenia, frequently seen in this group of patients, making procedures such as epidural injection less safe.

When a regional technique is considered viable, then the following need to be considered:

- the procedure should be carried out by adequately trained personnel
- regional techniques may be time-consuming and require additional staff to properly position the patient and assist the proceduralist
- regional techniques carry serious complications (e.g. subarachnoid injection of local anaesthetic or epidural haematoma during placement of epidural catheters) as well as the risk of local anaesthetic toxicity
- good preparation is paramount:
  - informed consent from patient or legal surrogate
  - recent normal coagulation profile or correction of abnormal profile. Platelet counts above 75 000/µL are recommended and antiplatelet agents (other than aspirin) should be ceased at an appropriate time interval beforehand
  - the knowledge of and ability to deal with complications
  - experience and knowledge of the drugs being used. Typically ropivacaine 0.2% is used for regional infusions and can be combined with an opioid, such as fentanyl 2 µg/mL or 4 µg/mL, for epidural infusion. Recommended maximum bolus doses and continuous infusion rates must be known. For ropivacaine; a single bolus of up to 3 mg/kg is allowed (to a maximum of 300 mg), while continuous infusion rates should not exceed 400 µg/kg/h
- adequate training of nursing staff to monitor the level of block in neuraxial techniques, haemodynamic parameters and for possible complications.

Within the context above, the following blocks may be useful in patients:

- femoral nerve block for hip and femur injuries; 20–40 mL of 0.2% ropivacaine injected intermittently 8–12-hourly into the region of the femoral nerve immediately inferior to the inguinal ligament
- intercostal or paravertebral nerve blocks or catheters for thoracic and upper abdominal injuries or wounds; 20 mL of 0.2% ropivacaine injected into the region of appropriate intercostal nerve – a single injection site has been shown to cover multiple nerve root levels[52]
- brachial plexus or intravenous regional anaesthesia for isolated upper limb injuries or procedures (e.g. fracture manipulation)
- epidural analgesia for thoracic and abdominal pain (e.g. flail chest, pancreatitis)
- intrapleural analgesia/anaesthesia, applied either via a catheter placed for this purpose or via intercostal drains previously placed for treatment of pneumothorax.

SLEEP

Although, outwardly, sedated patients resemble the sleep state, there are notable neurophysiological differences. Typically, critically ill patients have shorter periods of sleep, with a distinct reduction of slow-wave ‘deep’ sleep and rapid eye movement (REM) sleep.[53] Critically ill patients have poor sleep patterns due not only to their primary illness, but also to a host of other factors including:

- loss of the sleep–wake cycle after prolonged sedation
- pain
- invasive devices and monitoring
- the ICU environment
- nursing duties.

The importance of sleep disturbance in the critically ill on outcome is unknown, but there is concern over its contribution to delirium.[54]

Much of the focus on improving sleep in critically ill patients relies on non-pharmacological measures, addressing the sleep environment and sleep hygiene of the patient. Pharmacological agents such as BZAs may help patients get to sleep quicker and wake less often, but do not seem to improve the quality of physiological sleep.[54]

THE FUTURE

Research into sedation and analgesia in critically ill patients is intensifying. Areas where future study is focusing include:

- patient-controlled sedation
- target-controlled infusions (TCI) in intensive care
- automated/semiautomated sedation delivery systems[55]
- melatonergic agents for nocturnal sleep (e.g. ramelteon, valdoxane).

Inotropes and vasopressors

John A Myburgh

The pharmacological support of the failing circulation is a fundamental part of critical care. The principal aim of these drugs is to restore inadequate systemic and regional perfusion to physiological levels.

DEFINITIONS

Inotropic agents are defined as drugs that act on the heart by increasing the velocity and force of myocardial fibre shortening. The consequent increase in contractility results in increased cardiac output and blood pressure. Characteristics of the ideal inotrope are shown in **Box 90.1**.

Vasopressors are drugs that have a predominantly vasoconstrictive action on the peripheral vasculature, both arterial and venous. These drugs are used primarily to increase mean arterial pressure.

The distinction between these two groups of drugs is often confusing. Many of the commonly used agents such as the catecholamines have both inotropic and variable effects on the peripheral vasculature that include venoconstriction, arteriolar vasodilatation and constriction.

Vasoregulatory agents may modulate the responsiveness of the peripheral vasculature to vasoactive drugs in pathological states such as sepsis. These agents include vasopressin and corticosteroids.

Given the overlap of pharmacodynamic effects of these drugs, the term 'vasoactive therapy' is a more appropriate description.

THE FAILING CIRCULATION

PHYSIOLOGY

Traditionally, cardiac output is discussed in terms of factors that govern cardiac function. These include preload, afterload, heart rate and rhythm, and contractility. Although this perspective is helpful in managing patients whose circulatory function is limited by cardiac disease, it is incomplete.

Cardiac output is controlled by venous return to the heart from the peripheral vasculature at an equal rate to that ejected during each cardiac cycle[1] (**Fig. 90.1**).

Blood is pumped down a pressure gradient that is determined by the force of myocardial ejection (contractility) and impedance to ventricular ejection (afterload). The resultant mean arterial pressure is the major 'afferent' determinant of regional perfusion pressure. Twenty per cent of the blood volume is contained in the arterial ('conducting') vessels. There is a marked drop in perfusion pressure and flow across the capillary beds to allow diffusion of substrates and oxygen. The difference between mean arterial pressure and the pressure in end capillaries ('efferent' perfusion pressure) determines regional, or organ-specific, perfusion pressure.

Blood enters the venous system and is returned to the heart via a pressure gradient determined by mean systemic pressure and right atrial pressure. The amount of blood returned to the heart determines the degree of ventricular filling prior to systole (preload), which subsequently determines stroke volume and cardiac output.

Under physiological conditions, the venous ('capacitance') system contains approximately 70% of the total blood volume, which acts as a physiological reservoir ('unstressed' volume). Under conditions where circulatory demands increase, increased sympathetic tone will cause contraction of this reservoir.[2] The resultant autotransfusion ('stressed' volume) may increase venous return by approximately 30% and subsequently cardiac output.[3]

Both the arterial and venous systems are integrated under complex neurohormonal influences. These include the adrenergic, renin–angiotensin–aldosterone, vasopressinergic and glucocorticoid systems in addition to local mediators such as nitric oxide, endothelin, endorphins and the eicosanoids.[4]

PATHOPHYSIOLOGY

Circulatory dysfunction or failure may be considered in terms of the major determinants of cardiac output, although there is marked interdependence between these factors.

HEART RATE FAILURE

Profound bradycardia will reduce both cardiac output and mean arterial pressure if sympathetic tone is compromised. Inotropes will increase both rate and speed of conduction, in addition to augmenting peripheral

venous return, thereby restoring cardiac output and mean arterial pressure.

Tachycardia is associated with decreased left coronary artery perfusion, due to reduction of diastolic time, during which coronary perfusion occurs. This may exacerbate myocardial ischaemia in patients with coronary artery disease, particularly if mean arterial pressure, specifically diastolic blood pressure, is compromised. Therefore drugs that shorten diastolic time or compromise coronary perfusion should be used with caution in susceptible patients.

Box 90.1 The ideal inotrope

- Increases contractility
  - Increases mean arterial pressure
  - Increases cardiac output
  - Improves regional perfusion
- No increase in myocardial oxygen consumption
  - Avoidance of tachycardia
  - Non-arrhythmogenic
  - Maintenance of diastolic blood pressure
- Does not develop tolerance
- Titratable
  - Rapid onset
  - Rapid termination of action
- Compatible with other drugs
- Non-toxic
- Cost effective

PRELOAD FAILURE

Loss of intravascular blood volume or extracellular fluid is the most common cause of inadequate ventricular preload. This is corrected with fluids to maintain and restore a euvolaemia. Hypovolaemia must be recognised and treated as soon as possible, preferably before vasoactive therapy is used, although the early use of vasoactive therapy is increasingly being recommended.

There are other determinants of ventricular preload and venous return. Factors such as loss of muscle tone, positive intrathoracic pressure, loss of atrial contraction (atrial fibrillation) and ablation of sympathetic tone will compromise preload by reducing venous return. Under these circumstances, volume replacement alone may be insufficient to maintain adequate preload and vasoactive therapy may be required to increase venous return.

MYOCARDIAL FAILURE

Myocardial or 'pump' failure may be divided into disorders of systolic ejection (systolic dysfunction) and diastolic filling (diastolic dysfunction).

Systolic dysfunction occurs as a result of reduced effective myocardial contractility. This may be due to primary myocardial factors such as ischaemia,

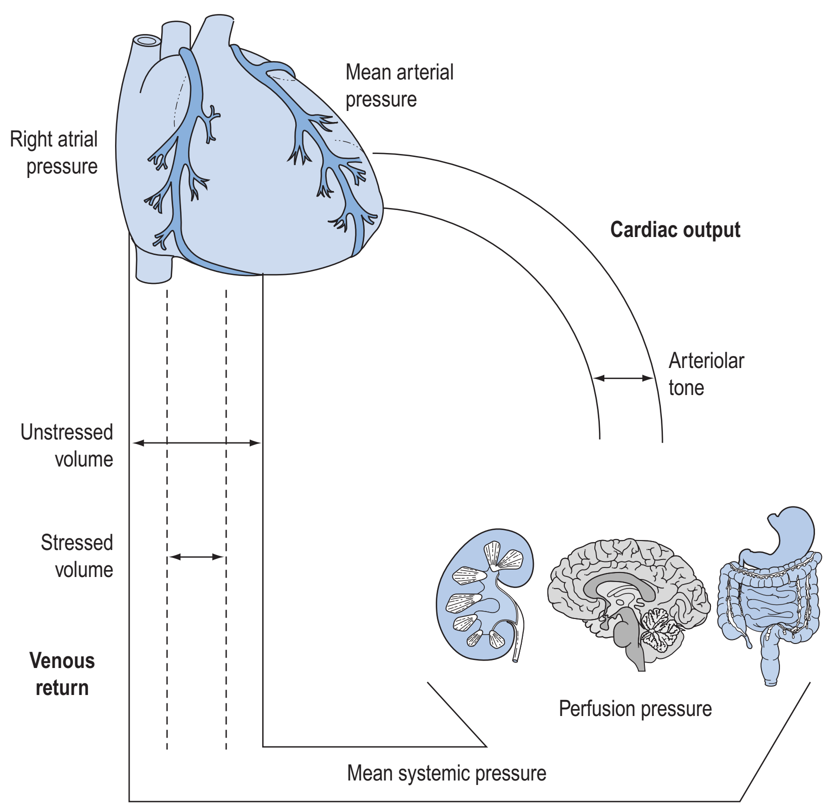

Figure 90.1 Schematic relationship of the determinants of cardiac output and venous return.

infarction or cardiomyopathy. Myocardial depression of both right and left ventricular function may occur in severe sepsis or following prolonged infusions of catecholamines. Increased impedance to ventricular ejection (e.g. hypertensive states) or structural abnormalities (e.g. aortic stenosis or hypertrophic obstructive cardiomyopathy) may cause systolic dysfunction.

Diastolic dysfunction is characterised by reduced ventricular compliance or increased resistance to ventricular filling during diastole. It may be due to mechanical factors such as structural abnormalities of the ventricle (e.g. restrictive cardiomyopathy) or to impaired diastolic relaxation that occurs with myocardial ischaemia or severe sepsis. This results in elevated end-diastolic pressure and pulmonary venous congestion. Episodic or 'flash' pulmonary oedema is a common clinical sign of diastolic dysfunction. Tachycardia that shortens diastolic time may exacerbate diastolic failure. Diastolic dysfunction frequently accompanies systolic failure, in both acute and chronic cardiac failure, particularly in elderly patients.

In the presence of systolic dysfunction, adequate stroke volume may be maintained by an increase in left ventricular end-diastolic volume (the Frank–Starling relationship), provided diastolic function is optimal. However, if the loss of effective myocardial mass is critical, the ventricle will be unable to maintain an adequate stroke volume and cardiac output will fall. In this situation, systolic dysfunction usually requires treatment with inotropic agents in order to augment stroke volume, thereby increasing cardiac output and mean arterial pressure.

VASOREGULATORY FAILURE

Disruption or impairment of regulation of the peripheral vasculature may result in circulatory failure. This includes acute sympathetic denervation, such as high quadriplegia, epidural or total spinal anaesthesia ('spinal' shock); distributive failure such as anaphylaxis; or pathological 'vasoplegia' that occurs in severe sepsis.

These syndromes are characterised by reduced responsiveness of the peripheral circulation to endogenous or exogenous sympathetic stimulation. This results in pooling in the venous circulation due to the inability to provide a 'stressed' volume.[5]

Management of these conditions has traditionally focused on the arterial circulation with attempts to increase systemic vascular resistance. However, the problem is predominantly impaired venous return, compounded to a lesser extent by pathological arteriolar vasodilatation.

Vasoactive agents may have a role in restoring vasoregulatory tone once adequate volume has been established.

CLASSIFICATION

The common ultimate cellular mechanism of action of these agents involves an influence on the release, utilisation or sequestration of intracellular calcium (**Fig. 90.2**). These agents are divided into two main groups based on whether or not their actions depend upon increases in intracellular cyclic adenosine 3,5-monophosphate (cAMP) and are outlined in **Table 90.1**.

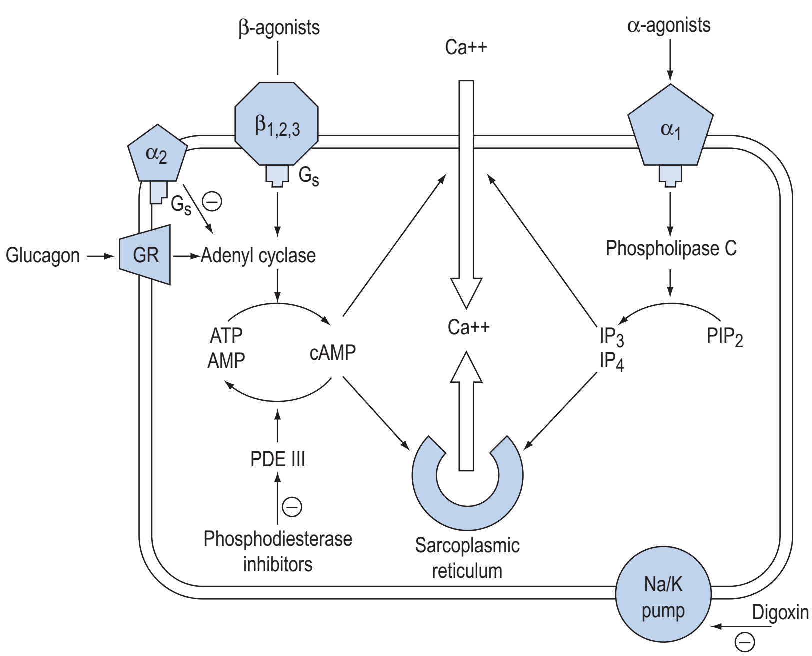

Figure 90.2 Schematic representation of the action of inotropic drugs on intracellular calcium in myocytes. GR=glucagon receptor; Gs=G protein complex; ATP=adenosine triphosphate, AMP=adenosine monophosphate; cAMP=cyclic AMP; PDE III=phosphodiesterase III; IP3=inositol phosphate 3, PIP2=phosphoinositol diphosphate.

Table 90.1 Classification of inotropes

cAMP DEPENDENT	cAMP INDEPENDENT
Catecholamines (beta-adrenergic agonists)	Catecholamines (alpha-adrenergic agonists)
Epinephrine (adrenaline)	Epinephrine (adrenaline)
Norepinephrine (noradrenaline)	Norepinephrine (noradrenaline)
Dopamine	Dopamine

Amrinone	
Milrinone	
Enoximone	
Levosimendan	
Calcium sensitisers	
Levosimendan	
Glucagon	

CATECHOLAMINES

Sympathomimetic amines are the most frequently used vasoactive agents in the intensive care unit (ICU) and include the naturally occurring catecholamines dopamine, norepinephrine (noradrenaline) and epinephrine (adrenaline), and the synthetic substances dobutamine, isoprenaline and dopexamine.

RECEPTOR BIOLOGY

Agonists bind to populations of adrenergic receptors, largely divided into α and β subgroups. Further subgroups of α- (α_{1A}, α_{1B}, α_{2A}, α_{2B}, α_{2C}) and β-receptors (β_1, β_2, β_3) have been identified.[4]

Signal transduction from agonist–receptor occupation to the effector cell is modulated by conformational changes in G proteins associated with these receptors. Under the additional influence of second messengers such as nitric oxide, endothelin and eicosanoids, these conformational changes promote the release of calcium from intracellular stores and increase membrane calcium permeability. Subsequent phosphorylation of substrate proteins via protein kinases act as third messengers to trigger a cascade of events that lead to specific cardiovascular effects.

β-Receptor occupancy predominantly activates adenyl cyclase to increase the conversion of adenosine triphosphate to cAMP. α-Receptor occupancy acts independently of cAMP by activation of phospholipase C, which increases inositol phosphates (IP_3 and IP_4) and diacyl glycerol.

This complex agonist–receptor–effector relationship is responsible for homeostatic mechanisms such as physiological responses to stress and autoregulation.

The activity and function of this system is dynamic and may be markedly influenced by pathological states. This may result in qualitative changes in the agonist–receptor–effector organ relationship (desensitisation) where receptors no longer respond to physiological or pharmacological sympathetic stimulation to the same extent. Quantitative changes such as reduced receptor density, receptor sequestration and enzymatic uncoupling (down-regulation) may also result in impaired responses.[6]

BIOSYNTHESIS

The biosynthesis and chemical structures of the naturally occurring catecholamines are shown in **Figure 90.3a**.

Catecholamines consist of an aromatic ring attached to a terminal amine by a carbon chain. The configuration of each drug is important for determining affinity to respective receptors.

Dopamine is hydroxylated to form norepinephrine, which is the predominant peripheral sympathetic chemotransmitter in humans, acting at all adrenergic receptors. The release of norepinephrine from sympathetic terminals is controlled by reuptake mechanisms mediated via α_2-receptors and augmented by epinephrine released from the adrenal gland at times of stress. Norepinephrine is converted to form epinephrine, which is subsequently metabolised in liver and lung.

All catecholamines have very short biological half-lives (1–2 minutes) and a steady state plasma concentration is achieved within 5–10 minutes after the start of a constant infusion. This allows rapid titration of drug to a clinical end-point such as mean arterial pressure.

Epinephrine and norepinephrine infusions produce blood concentrations similar to those produced endogenously in shock states, whereas dopamine infusions produce much higher concentrations than those naturally encountered. Dopamine may exert much of its effect by being converted to norepinephrine, thus bypassing the rate-limiting (tyrosine hydroxylase) step in catecholamine synthesis.

The synthetic catecholamines are derivatives of dopamine (Fig. 90.3b). These agents are characterised by increased length of the carbon chain, which confers affinity for β-receptors. Dobutamine is a synthetic derivative of isoprenaline. These agents have relatively little affinity for α-receptors due to the configuration of the terminal amine, which differs from the endogenous catecholamines.

Epinephrine, norepinephrine and isoprenaline all have hydroxyl groups on the β-carbon atom of the side chain, and this is associated with 100-fold greater potency than dopamine or dobutamine.

SYSTEMIC EFFECTS

The systemic effects of any of these agents will vary greatly between patients and within individuals at

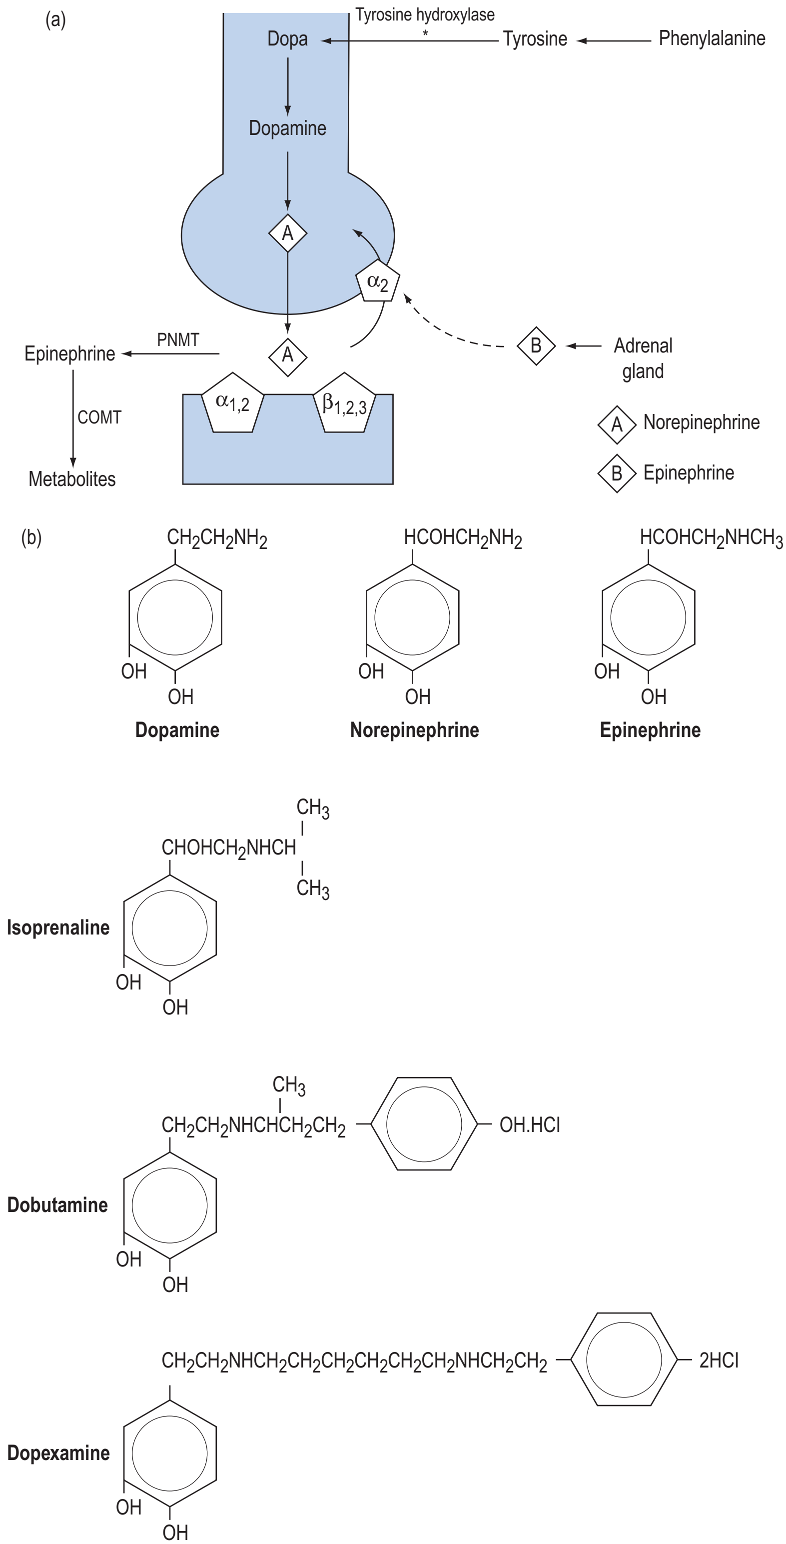

Figure 90.3 **(a)** Biosynthesis of catecholamines in sympathetic terminals. *=rate-limiting step by tyrosine hydroxylase; PNMT=phenethanolamine-*N*-methyltransferase, COMT=catechol-*o*-methyl-transferase. **(b)** Chemical structure of endogenous and synthetic catecholamines.

different times. Adequacy of response is often unpredictable and depends on the aetiology of circulatory failure and systemic co-morbidities. In some patients, dramatic responses to small doses may occur, whereas in others large doses of inotropes may be required to support the failing circulation.

The classification of sympathomimetic agents into alpha and beta agonists, based on the above structure–function relationships, is only a crude predictor of systemic effects.

Epinephrine, norepinephrine and dopamine are all predominantly beta agonists at low doses, with increasing α-effects becoming evident as the dose is increased.

The synthetic catecholamines are all predominantly beta agonists.

CARDIOVASCULAR

The cardiovascular effects of the catecholamines under physiological conditions are shown in **Table 90.2**.

Norepinephrine, epinephrine and dopamine all tend to increase stroke volume, cardiac output and mean arterial pressure, with little change in heart rate. Dopamine is associated with an increased incidence of dysrhythmias.[7] The effects on the peripheral vasculature are similar, with all agents increasing venous return without significant changes in calculated systemic vascular resistance.

Isoprenaline increases cardiac output predominantly by increasing heart rate and by moderate inotropy. This occurs without a significant change in blood pressure due to predominant β_2-receptor-induced veno- and vasodilatation.

The profile of dobutamine is similar to isoprenaline, although increases in heart rate are not as pronounced. Both of these agents may decrease mean arterial pressure, particularly in hypovolaemic patients, due to reduced venous return caused by venodilatation. The adverse effects of dobutamine and isoprenaline on heart rate and mean arterial pressure may compromise patients with ischaemic heart disease.

In the failing myocardium, particularly in patients with cardiac failure following cardiopulmonary bypass or septic shock, endogenous stores of norepinephrine are markedly reduced.[8] Furthermore, there may be significant desensitisation and down-regulation of cardiac β-receptors. In these situations, α_1- and α_2-receptors have an important role in maintaining inotropy and peripheral vasoresponsiveness.[9] This may be expressed clinically as 'tolerance' or tachyphylaxis to catecholamines, particularly with predominantly beta agonists such as dobutamine. This phenomenon may explain the requirement for high doses of catecholamines in refractory shock states. Consequently, the role of beta agonists in patients with severe myocardial failure has been questioned.

Catecholamines have a significant effect on the venous circulation. These drugs primarily restore or maintain 'stressed volumes' of the capacitance vessels under pathological conditions, thereby maintaining or increasing cardiac output and mean arterial pressure. This is important in 'vasoplegic' states such as septic shock.[5]

In clinically used doses, intravenously administered catecholamines have minimal direct vasoconstrictive effects on conducting arterial vessels.

The development of peripheral gangrene in refractory septic shock has been attributed to catecholamine-induced vasoconstriction. There is little evidence to support this as the development of tissue gangrene in these situations primarily occurs as a consequence of intravascular thrombosis caused by sepsis-mediated coagulopathy.

CEREBRAL

Under physiological conditions, catecholamines do not normally cross the blood–brain barrier. Cerebral blood flow is maintained at a constant rate over a range of perfusion pressure by cerebral autoregulation. Under conditions where the integrity of the blood–brain barrier is altered, such as following traumatic brain

Table 90.2 Cardiovascular effect of catecholamines

AGENT	β_1 EFFECTS	β_2 EFFECTS	α_1 EFFECTS	α_2 EFFECTS
	+ chronotropy + dromotropy + inotropy	+ inotropy vasodilatation bronchodilatation	+ inotropy vasoconstriction	+ inotropy vasoconstriction
Norepinephrine Epinephrine Dopamine	β effects predominate at low dose; α effects predominate at high dose			
Dobutamine	+	+	(+)	–
Isoprenaline	+	(+)	–	–
Dopexamine	+	+	–	–

+=stimulation; (+)=mild effect; –=no effect.

injury and aneurysmal subarachnoid haemorrhage, exogenous catecholamines may directly enter the cerebral circulation.

The degree by which these agents directly affect the cerebral circulation following head injury is unknown, although there is some evidence suggesting that dopamine has a direct effect causing increased cerebral blood flow and intracranial pressure.[10]

RENAL

The kidney is an efficient autoregulator, maintaining constant glomerular filtration and renal blood flow by neurohumoral mechanisms such as the renin–angiotensin–aldosterone system.[11] All catecholamines will increase renal blood flow to a similar extent because of increased cardiac output and mean arterial pressure with a resultant natriuresis. Catecholamine-mediated increases in renal blood flow do not affect glomerular filtration rate.

A direct natriuresis may also result from inhibition of cAMP in the renal tubules. This effect has been attributed primarily to low doses of dopamine (2 μg/kg per min), although this occurs to a similar extent with epinephrine, norepinephrine and dobutamine. The use of low-dose ‘renal’ dopamine has been shown to be ineffective in preventing renal dysfunction in susceptible patients.[12]

SPLANCHNIC

Splanchnic autoregulation is not as robust as the brain and kidney. Perfusion is more dependent on mean arterial pressure and the duality of the mesenteric and portal systems. Concerns about catecholamine-induced splanchnic vasoconstriction with mesenteric and hepatic ischaemia have not been substantiated.[13]

Dopamine and dopexamine have been promoted as selective splanchnic vasodilators, but there are no conclusive studies indicating a significant benefit over norepinephrine or epinephrine. Many studies have used gastric intramucosal pH (pHi), a surrogate measurement of splanchnic blood flow, as the primary endpoint. However, as pHi remains an unvalidated measurement, the results of many of the comparative trials of the different sympathomimetics are inconclusive. All catecholamines are equally effective in increasing splanchnic perfusion by improving cardiac output and mean arterial pressure.

METABOLIC

Catecholamine-mediated β-stimulation may result in hyperglycaemia, hypokalaemia and hypophosphataemia, which may need monitoring and correcting.

Epinephrine is associated with the development of hyperlactataemia and acidaemia, due to activation of pyruvate dehydrogenase. Although pH may fall to levels around 7.2, the acidosis is not associated with impaired tissue perfusion or cellular dysoxia. In most patients who are haemodynamically stable, this is a self-limiting phenomenon and is not associated with adverse outcomes.[14,15]

NON-CATECHOLAMINES

PHOSPHODIESTERASE INHIBITORS

Phosphodiesterase inhibitors are compounds that cause non-receptor-mediated competitive inhibition of phosphodiesterase isoenzymes (PDE), resulting in increased levels of cAMP (see Fig. 90.2). Importantly, cAMP also affects diastolic heart function through the regulation of phospholamban, the regulatory subunit of the calcium pump of the sarcoplasmic reticulum. This enhances the rate of calcium resequestration and thereby diastolic relaxation.

For cardiovascular tissue, inhibition of isoenzyme PDE III is responsible for the therapeutic effects. Cardiac effects are characterised by positive inotropy and improved diastolic relaxation. The latter is termed lusitropy and may be beneficial in patients with reduced ventricular compliance or predominant diastolic failure.[16]

These agents also cause potent vasodilatation with reductions in preload, venous return and afterload as well as a reduction in pulmonary vascular resistance. The term ‘inodilation’ has been used to describe this dual haemodynamic effect.

Tolerance is not a feature. These agents may have a place in the management of patients with β-receptor down-regulation by causing intrinsic inotropic stimulation and by sensitising the myocardium to beta agonists. Other actions include inhibition of platelet aggregation and reduction of post-ischaemic reperfusion injury.

The pharmacokinetics of phosphodiesterase inhibitors are markedly different from catecholamines. Drug half-lives may be prolonged and excretion is predominantly renal. Hypotension may result from vasodilatation and combined use with catecholamines (e.g. norepinephrine or epinephrine) may be necessary to maintain mean arterial pressure.

Phosphodiesterase inhibitors that have been used in clinical practice include the bipyridine derivatives amrinone and milrinone, the imidazolones enoximone and piroximone, and the calcium sensitiser levosimendan. The cardiovascular effects are similar.

Milrinone is the most commonly used drug in clinical practice, with the latter exhibiting more inotropic effects than vasodilatation. Enoximone is more rapidly metabolised, but the metabolite is active and its cardiovascular effects persist for some hours.

Levosimendan is a dose-dependent selective phosphodiesterase inhibitor with a unique action on myocardial calcium metabolism.[17] By increasing myofilament calcium sensitivity throughout the cardiac cycle by binding to cardiac troponin C, associated

conformational changes induce improved inotropic and lusitropic function. Vasodilatation is also induced through ATP-sensitive potassium channels. Calcium-sensitive actions predominate at low doses, whereas PDE-inhibition effects predominate at higher doses. The half-life of levosimendan is shorter than that of older PDE III inhibitors (approximately 1 hour) and it may be given by infusion.

HISTORICAL DRUGS

DIGOXIN

Digitalis glycosides have been used for the treatment of heart failure for 200 years and the vagotonic effects used to control the ventricular response in selected supraventricular tachyarrhythmias. Its use in the ICU has been superseded by catecholamines and antiarrhythmics such as amiodarone, although the role of digoxin in chronic heart failure is well established.

The role of digoxin in acute cardiac failure is limited. It has minimal effects as an inotrope and evaluation of its efficacy is difficult. The potential for toxicity in the critically ill patient is increased by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia and acidosis. Toxicity is manifested by dysrhythmias that may assume any form including supraventricular tachyarrhythmias, bradycardia, ventricular ectopy and conduction block at any level.

GLUCAGON

Glucagon is a naturally occurring polypeptide that directly stimulates adenyl cyclase via specific receptors to increase cAMP concentration in myocardial cells resulting in positive inotropy without producing myocardial excitability. No definitive cardiovascular role for this agent has been established apart from anecdotal reports of its use in severe beta-blocker and tricyclic poisoning.

THYROID HORMONE

Thyroid hormone is required for synthesis of contractile proteins and normal myocardial contraction. It is also a regulator of the synthesis of adrenergic receptors. Its use is limited in critically ill patients, but may have a limited, although unproven, role in haemodynamic support of brain-dead organ donors as a catecholamine-sparing agent.

SELECTIVE VASOPRESSORS

Vascular responsiveness is mediated via adrenergic receptors: α-mechanisms predominantly cause vasoconstriction; β-mechanisms, specifically β_2-receptors, mediate vasodilatation (see Table 90.2).

Norepinephrine, epinephrine and dopamine have variable effects on the peripheral vasculature and should not be regarded principally as vasoconstrictors or vasopressors.

There are few selective 'vasoconstrictors' that predominantly have a role in vasodilated states such as regional (epidural) anaesthesia or selected patients with acute spinal injury. Their utility in critically ill patients remains limited and they have an unproven role in patients with catecholamine-resistant septic shock and cardiopulmonary resuscitation.

PHENYLEPHRINE AND METARAMINOL

These agents are direct-acting alpha-2 agonists that are selective vasoconstrictors, both venous and arterial, with minimal beta activity. They have similar pharmacokinetics to catecholamines and may be given by infusion. In patients with normal sympathetic tone, these drugs may cause reflex bradycardia, particularly following bolus administration.

EPHEDRINE

Ephedrine is a synthetic, direct- and indirect-acting, non-catecholamine sympathomimetic that acts on both α- and β-receptors. Duration of action is longer than equivalent doses of epinephrine and it is generally unsuitable as an infusion.

VASOREGULATORY AGENTS

In addition to adrenergic regulation, neurohumoral influences have a 'permissive' or regulatory role in maintaining vasomotor tone. These are mediated through the renin–aldosterone–angiotensin axis and local mediators such as vasopressin, corticosteroids, nitric oxide and endothelin.

The response of the whole neurohumoral system may become blunted in conditions such as severe sepsis, where qualitative and quantitative changes may occur. In this context, failure of vasomotor responsiveness may be considered as part of the multiple organ failure.

VASOPRESSIN

Specific vasopressinergic receptors (V_1, V_2) have been identified in association with sympathetic terminals. Vasopressin is a naturally occurring peptide secreted by the posterior pituitary gland. Reduced serum levels of vasopressin have been demonstrated in septic shock and following cardiopulmonary bypass, suggesting an inflammatory-mediated mechanism. Levels are maintained during cardiogenic shock.

A proportion of patients with severe septic shock requiring high levels of catecholamines to support the circulation may respond to low doses of infused vasopressin (0.04 U/h). However, although vasopressin may improve catecholamine responsiveness in patients

with less-severe shock, no benefit in mortality has been demonstrated and there is uncertainty about its use in shock states.[18]

STEROIDS

The role of steroid supplementation in circulatory failure has been studied for many years. Although immunosuppressive or anti-inflammatory doses have been shown to be ineffective, particularly in septic shock, replacement of 'stress response' doses (approximately 100–200 mg hydrocortisone per day) have been shown to improve catecholamine vasoresponsiveness in selected patients with septic shock.[19] However, the role of steroids in shock states remains uncertain, despite two large trials, and they are not routinely recommended.[20,21]

CLINICAL USES

Currently, there are no definitive studies comparing the efficacy of one inotrope (or combination of inotropes) over another in terms of improving survival.[22]

DRUG SELECTION

In most instances, individual experience and preference determine selection of inotrope(s).

On a pathobiological basis, exogenous catecholamines are essentially used to augment endogenous mechanisms that may be failing at a number of levels. In this context, vasoactive therapy should be regarded as 'cardiovascular neuroendocrine augmentation therapy'.

Norepinephrine or epinephrine may be considered as the first-line drug in most causes of circulatory failure. An emerging body of evidence confirms this statement.[7,14,15]

Dopamine predominantly acts as a precursor of norepinephrine and may be used as an alternative to norepinephrine, although it is associated with an increased incidence of arrhythmias.[7]

Prediction of the response of an individual to a catecholamine is problematic as marked inter- and intra-individual variability to the response of inotropic agents may occur.

The haemodynamic and metabolic response of an agent must be carefully monitored and evaluated. If there is not a satisfactory response, or if undesirable effects are obtained, the dose or agent should be changed.

MONITORING

Accurate monitoring of the circulation is essential in patients with circulatory failure to assess baseline parameters and the response of vasoactive drugs.

Clinical assessment of the circulation remains the cornerstone of monitoring these patients and includes frequent assessment and recording of pulse rate and rhythm, blood pressure, adequacy of peripheral perfusion, skin turgor, level of consciousness and urine output.

The majority of patients with circulatory failure managed in the ICU require haemodynamic monitoring as clinical signs may be masked or influenced by sedation, ventilation or organ failure. As a minimum, all patients receiving vasoactive drugs in all but trivial doses should have accurate monitoring of mean arterial pressure, ideally with an intra-arterial catheter referenced to the aortic root and an assessment of volume status such as central venous pressure.

In selected patients with primary myocardial failure, an assessment of cardiac output may be useful to quantify baseline function and to assess the response of the heart to drug therapy. Measurement of cardiac output may be done non-invasively using transthoracic or transoesophageal echocardiography or invasively using a pulmonary catheter, ideally using a continuous cardiac output display system, although the use of these catheters has decreased substantially.

Systemic vascular resistance is frequently calculated and used as a surrogate index of afterload. However, the clinical utility of systemic vascular resistance is limited to providing a crude estimate of global vascular tone, as it does not reflect afterload, arteriolar tone or venous return. Consequently, systemic vascular resistance should not be used as a criterion for selection of vasoactive drug or as a titratable end-point.

Restoration of reduced tissue perfusion is a primary aim of vasoactive therapy. This may be assessed clinically by improvements in urine output, serum urea and creatinine, reversal of metabolic acidosis and reduction in serum lactate.

DOSAGES AND DRUG ADMINISTRATION

Vasoactive drugs, such as catecholamines or vasopressors, are administered by continuous infusion through a dedicated central venous catheter using drug delivery systems such as infusion pumps or syringe drivers.

Infusion lines should be free of injection portals and clearly marked with identifying labels.

Concentrations of infusions should be standardised in accordance with individual unit protocols. Suggested infusion concentrations are shown in **Table 90.3**.

These infusions in mL/hour approximate μg/min. Absolute doses with regard to body weight are not relevant; rather it is the titrated clinical effect. Vasoactive drugs are usually prescribed as a titration against a desired mean arterial pressure.

CARDIOPULMONARY RESUSCITATION

Epinephrine has been used for circulatory collapse at least since 1907. The International Liaison Committee on Resuscitation guidelines recommends epinephrine as first-line vasoactive drug in cardiopulmonary

Table 90.3 Infusion concentrations of commonly used vasoactive drugs

AGENT	INFUSION CONCENTRATION	DOSE
Epinephrine	6 mg/100 mL 5% dextrose	Titrate mL/h (=μg/min)
Norepinephrine	6 mg/100 mL 5% dextrose	Titrate mL/h (=μg/min)
Dopamine	400 mg/100mL 5% dextrose	Titrate mL/h (approx μg/kg/min)
Dobutamine	500 mg/100 mL 5% dextrose	Titrate mL/h (approx μg/kg/min)
Isoprenaline	6 mg/100 mL 5% dextrose	Titrate mL/h (=μg/min)
Milrinone	10 mg/100 mL 5% dextrose	Loading dose: 50 μg/kg over 20 min Infusion: 0.5 μg/kg/min
Levosimendan	25 mg/100 mL 5% dextrose	Loading dose: 24 μg/kg over 10 min Infusion: 0.1 μg/kg/min
Phenylephrine	10 mg/100 mL 5% dextrose	Titrate mL/h (=100 μg/h)
Metaraminol	100 mg/100 mL 5% dextrose	Titrate mL/h (=mg/h)
Ephedrine	300 mg/100 mL 5% dextrose	Titrate mL/h (=3 mg/h)
Vasopressin	20 units/20 mL 5%dextrose	2.4 mL/h (0.04 u/min)
Hydrocortisone	100 mg/100 mL 5% dextrose	Loading dose: 100 mg Infusion: 0.18 mg/kg/h

resuscitation. Doses are 1 mg intravenously every 3 minutes.[23]

Epinephrine is recommended as first-line therapy for 'medical pacing' for severe bradyarrhythmias that do not respond to atropine. Isoprenaline has traditionally been used for this purpose; however, its use has been superseded by epinephrine due to concerns about efficacy and lack of alpha-adrenergic activity.

CARDIOGENIC SHOCK

Theoretically, catecholamine infusions may confer some advantages in cardiogenic shock, particularly in association with acute myocardial infarction. In patients with systolic heart failure, epinephrine, norepinephrine, dopamine and dobutamine have been shown to cause satisfactory short-term effects. This may allow the myocardium time to recover from post-ischaemic 'stunning', particularly after revascularisation. However, no increased long-term survival due to their use has been demonstrated.[24]

The role of phosphodiesterase inhibitors (e.g. milrinone) and calcium sensitisers (e.g. levosimendan) in acute heart failure has yet to be determined, but they may have a potential role in patients with diastolic heart failure, particularly those with associated high impedance states such as aortic stenosis and pulmonary hypertension. Due to their non-adrenergic mechanism of action, these agents may be useful in patients who are 'resistant' to catecholamines.

SEPARATION FROM CARDIOPULMONARY BYPASS

Numerous combinations of catecholamines have been used successfully to wean patients from cardiopulmonary bypass. However, there are no definitive studies demonstrating significant benefits of one catecholamine over another. Similarly, the question whether mechanical support devices, such as intra-aortic counterpulsation, offer a significant advantage over inotropes following cardiac surgery remains unanswered.

Epinephrine and norepinephrine have been found to increase cardiac output with little increase in heart rate or afterload and are often regarded as first-line drugs. Dobutamine may be associated with vasodilatation and hypotension.

There is no conclusive evidence that the catecholamines, including norepinephrine, cause vasospasm of arterial conduits in clinically used doses.

Phosphodiesterase inhibitors, such as milrinone and levosimendan, either as sole agents or in conjunction with epinephrine or norepinephrine, have been used with success. These may have a role following mitral valve replacement in patients with pulmonary hypertension or preoperative diastolic failure.[25]

Cardiopulmonary bypass may be associated with a systemic inflammatory response syndrome characterised by a hyperdynamic, vasodilated 'low systemic vascular resistance' state. Norepinephrine is frequently advocated as a 'vasopressor' agent in this context to restore mean arterial pressure, which may be reduced as a consequence. Although catecholamines may be required to achieve appropriate target mean arterial pressure and cardiac output, caution should be applied if high doses (e.g. >30 μg/min norepinephrine) are required. This may be associated with tachyphylaxis and potentiation of catecholamine dependency.[26]

RIGHT VENTRICULAR FAILURE

Right ventricular infarction and major pulmonary embolism may be associated with acute right ventricular failure. Right ventricular depression may also occur in severe sepsis. Restoration of preload is critical in these conditions, as the failing right ventricle is particularly susceptible to reductions in preload.[27]

Inotropes such as norepinephrine and epinephrine are regarded as first-line drugs in these situations in order to maintain adequate mean arterial pressure so that right coronary artery perfusion, which occurs throughout the cardiac cycle, is maintained.

SEPTIC SHOCK

The cardiovascular effects of the sepsis syndrome and septic shock are complex and range from a hyperdynamic, vasodilated state to one of increasing myocardial failure and paralysis of the peripheral v asculature (vasoplegia). The latter represents inability of the venous circulation to respond to endogenous or exogenous catecholamines with resultant venous pooling.

An increasing body of literature now recommends the use of catecholamines as first-line agents in the treatment of septic shock. The Surviving Sepsis Campaign guidelines recommend either norepinephrine or epinephrine be used as the first-line choice vasopressor.[28] However, the basis for this recommendation is limited as there is no high-quality evidence to recommend one catecholamine over another.[22] Concerns about adverse metabolic and splanchnic side-effects of epinephrine are unsubstantiated, and there is an emerging body of evidence that norepinephrine and epinephrine are equally effective in treating septic shock.[14,15] There is evidence that dopamine may be associated with adverse outcomes[7] and its use is being questioned in the absence of superiority to norepinephrine or epinephrine.

The efficacy of dobutamine as a sole agent or in combination with norepinephrine in septic shock is questionable and appears to add little to the efficacy of norepinephrine or epinephrine in terms of resolution of shock or mortality.

Doses required to achieve adequate mean arterial pressure in septic shock may vary: norepinephrine or epinephrine infusions (up to 40 μg/min) may be necessary. Patients who develop marked catecholamine dependency, in the absence of other acute remediable causes such as active infection, may respond to low doses of vasopressin or 'stress response' doses of hydrocortisone, although there is marked interindividual variation in response to these drugs.

ANAPHYLAXIS

Epinephrine is the drug of choice for anaphylactic reactions and for life-threatening bronchospasm, as it blocks mediator release and specifically reverses end-organ effects (see Ch. 66).

A dose of 0.1 mg, as 1 mL of 1:10 000 solution, may be injected subcutaneously, intramuscularly or intravenously. Repeated doses or infusions of up to 100 μg/min may be required. A strong slowing pulse indicates a pressor effect and provides a useful clinical end-point for the rate of infusion. This alpha-agonist effect is probably also of considerable importance in anaphylaxis, as deaths are frequently due to prolonged refractory hypotension caused by acute biventricular failure. Early intravenous fluid therapy is also important.

RENAL PROTECTION

'Renal' dose dopamine (2 μg/kg per min) had been advocated for many years as a renal protective agent by causing renal vasodilatation. However, this has not been substantiated in controlled clinical trials in susceptible patients or as an adjunctive agent with other inotropes in septic shock.[12] Consequently low-dose dopamine is no longer recommended.

CEREBRAL PERFUSION PRESSURE

Augmentation of cerebral perfusion pressure is an important strategy in patients with pathological reductions in cerebral blood flow, such as traumatic brain injury and subarachnoid haemorrhage. Norepinephrine and epinephrine have been used to augment cerebral perfusion pressure, although there is no conclusive evidence to recommend one drug over another.[10]

Vasodilators and antihypertensives

Anthony C Gordon and John A Myburgh

Vasodilators are a generic group of drugs that are primarily used in the intensive care unit (ICU) for the management of acute hypertensive states and emergencies. In addition, they have an important role in the management of myocardial ischaemia, systemic and pulmonary hypertension and cardiac failure.[1]

PHYSIOLOGY

Blood pressure is controlled by a complex physiological neurohormonal system involving all components of the cardiovascular system.[2,3] Traditionally, clinical practice has focused on the arterial circulation as the major regulator of systemic pressure. The importance of venous circulation in determining mean arterial pressure and cardiac output is discussed in Chapter 90.

The role of the peripheral vasculature, including both arteriolar and venous systems, in the regulation of blood pressure may be conceptually regarded as a balance between vasodilatation and vasoconstriction[3] (**Fig. 91.1**).

CALCIUM FLUX

The concentration of intracellular ionised calcium is the primary determinant of vascular smooth muscle tone: increases lead to smooth muscle contraction; decreases cause relaxation. Control of calcium influx and efflux is determined by adrenergic receptor occupation and changes in membrane potential, mediated through voltage-gated channels (see Ch. 90, Fig. 90.2).

ENDOTHELIAL SYSTEM

The endothelium plays a central role in blood pressure homeostasis by secreting substances such as nitric oxide, prostacyclin and endothelin.[3] These substances are continuously released by the endothelium and are integral in regional autoregulation.[4]

Nitric oxide is synthesised from L-arginine by nitric oxide synthases and diffuses into underlying smooth muscle where it activates guanylate cyclase to increase cyclic guanosine monophosphate (cGMP) resulting in relaxation of underlying smooth muscle and vasodilatation.

Prostacyclin is synthesised via the arachidonic pathway and has a minor role in the control of vascular tone.

Endothelins are endothelium-derived vasoconstrictor peptides that are associated with increases in vascular smooth muscle intracellular calcium. They bind to endothelin receptors within the vascular smooth muscle and lead to vasoconstriction, usually in response to shear stresses, tissue hypoxia, angiotensin II and inflammatory mediators (e.g. interleukin-6 and nuclear factor-κB (NF-κB)).

RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM

Angiotensinogen is converted by renin to form angiotensin I, which is subsequently converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has a number of effects that are responsible for blood pressure homeostasis. These include release of aldosterone, direct activation of alpha-adrenergic (α-adrenergic) receptors on vascular smooth muscle and a direct effect in the endothelium. These effects are directed at maintaining blood pressure and are integral in the stress response. Angiotensin-converting enzyme is also responsible for the inactivation of bradykinins that have predominantly vasodilatory effects, coupled to arachidonic acid synthesis and generation of prostacyclin.

ADRENERGIC SYSTEM

The sympathetic nervous system is integrally involved with all of the above systems, regulating vascular tone at central, ganglionic and local neural levels. Adrenergic stimulation of β-receptors is associated with vasodilatation; α-receptor stimulation results in vasoconstriction. The vascular effects of the catecholamines and vasopressors are discussed in Chapter 90.

Adrenergic stimulation is the predominant system in regulating venous tone.[5] This is due to endothelial differences in veins resulting in less production of nitric oxide and reduced responsiveness to angiotensin II.

PATHOPHYSIOLOGY

Hypertensive states develop as a result of impaired or abnormal homeostatic processes, causing an imbalance between vasoconstrictive and vasodilatory effects.

Essential hypertension is the most common cause of hypertension and is due to abnormal neurohormonal

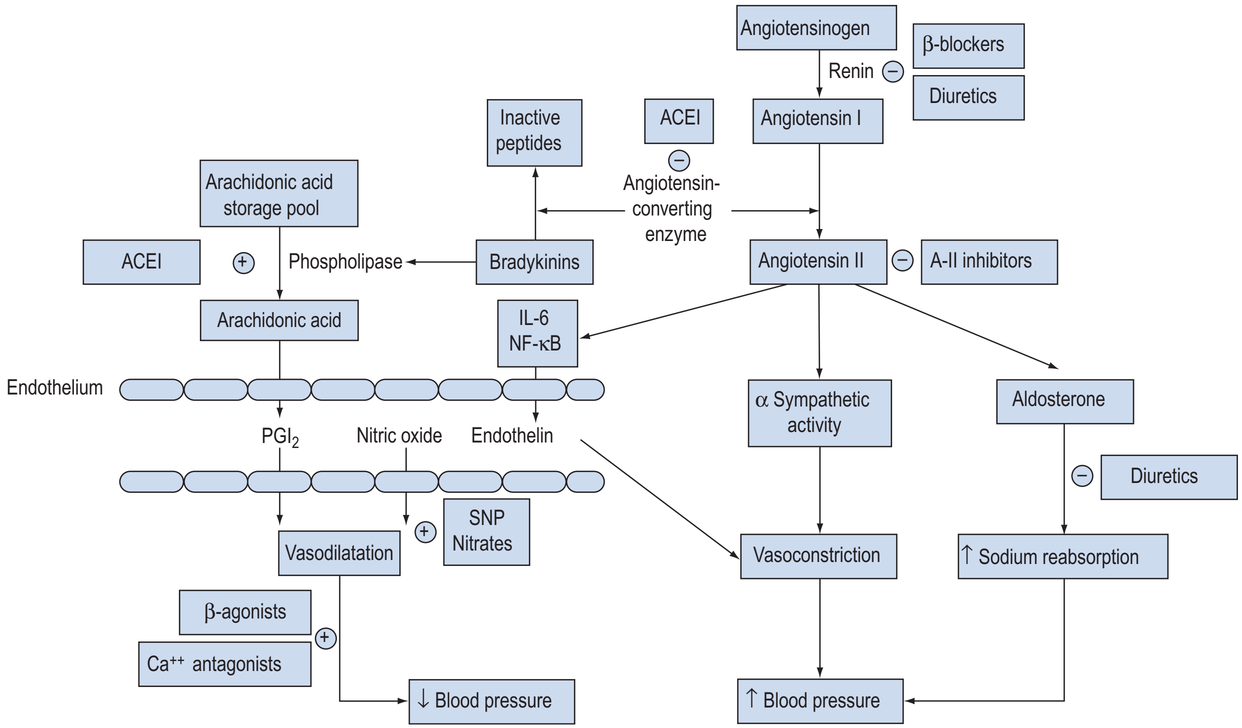

Figure 91.1 Schematic diagram of the neurohormonal factors determining vasomotor tone. Mechanism of action of vasodilators is shown by (–) for inhibition, (+) for stimulation. ACEI = angiotensin-converting enzyme inhibitors; A-II = angiotensin II; IL = interleukin; NF = nuclear factor; PGI_2 = prostacyclin; SNP = sodium nitroprusside.

regulation, particularly exaggerated effects of renin–angiotensin activity.

Secondary causes of hypertension include structural abnormalities such as aortic stenosis or renal artery stenosis; endocrine conditions such as phaeochromocytoma, Cushing's syndrome and pregnancy-induced hypertension; and central causes such as hypertensive encephalopathy or raised intracranial pressure.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers have numerous effects on the cardiovascular system, influencing heart rate conduction, myocardial contractility and vasomotor tone. Entry of calcium through voltage-gated calcium channels is a major determinant of arteriolar, but not venous, tone.[6] Calcium channel blockers are recommended as first-step treatment for hypertension in Caucasian patients >55 years and Afro-Caribbean patients of any age.[7]

There are three major groups of calcium channel blockers that have different sites of action and thus different therapeutic effects: dihydropyridines (e.g. nifedipine, nimodipine, nicardipine, amlodipine, felodipine and clevidipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem).

Magnesium is a physiological calcium antagonist, and is used therapeutically as magnesium sulphate.

NIFEDIPINE

Nifedipine is a predominant arteriolar vasodilator, with minimal effect on venous capacitance vessels and no direct depressant effect on heart rate conduction.

It may be administered intravenously, orally or sublingually, and has a rapid onset of action (2–5 minutes) and duration of action of 20–30 minutes.

Nifedipine can be used to treat angina pectoris, especially that due to coronary artery vasospasm. Peripheral vasodilatation results in decreased systemic blood pressure, often associated with sympathetic stimulation resulting in increased cardiac output and heart rate, which may counter the negative inotropic, chronotropic and dromotropic effects of nifedipine. Nevertheless, nifedipine may be associated with profound hypotension in patients with ventricular dysfunction, aortic stenosis and/or concomitant beta blockade. For this reason, the use of sublingual nifedipine as a method of treating hypertensive emergencies is no longer recommended.[8]

Nifedipine and related drugs may cause diuretic-resistant peripheral oedema that is due to redistribution

of extracellular fluid rather than sodium and water retention.

NIMODIPINE

Nimodipine is a highly lipid-soluble analogue of nifedipine. High lipid solubility facilitates entrance into the central nervous system where it causes selective cerebral arterial vasodilatation.

It may be used to attenuate cerebral arterial vasospasm following aneurysmal subarachnoid haemorrhage. Improved outcomes have been demonstrated in patients with Grade 1 and 2 subarachnoid haemorrhage.[9] Systemic hypotension may result from peripheral vasodilatation that may compromise cerebral blood flow in susceptible patients. Similarly, cerebral vasodilatation may increase intracranial pressure in patients with reduced intracranial elastance.

The recommended dose following aneurysmal subarachnoid haemorrhage is 60 mg orally 4-hourly, but it can be given at 30 mg 2-hourly to reduce variation in blood pressure. The use of intravenous nimodipine is not recommended owing to its profound effect on blood pressure.

AMLODIPINE

Amlodipine is an oral preparation that has a similar pharmacodynamic profile to nifedipine. In addition to arteriolar vasodilatory and cardiac effects, amlodipine has been shown to exert specific anti-inflammatory effects in hypertension, diabetic nephropathy and in modulating high-density lipoprotein (HDL) in patients with hypercholesterolaemia.[10] These effects have seen amlodipine increasingly being used for treatment of hypertension in high-risk patients, and may have a role in stable critically ill patients with associated comorbidities.

VERAPAMIL

The primary effect of verapamil is on the atrioventricular node and this drug is principally used as an antiarrhythmic for the treatment of supraventricular tachyarrhythmias. For this reason, concomitant therapy with beta blockers or digoxin is not recommended.

Verapamil is not as active as nifedipine in its effects on smooth muscle and it therefore causes less pronounced decrease in systemic blood pressure and is also negatively inotropic. It has a limited role as a vasodilator.[11]

DILTIAZEM

Diltiazem has a similar cardiovascular profile to verapamil, although its vasodilatory properties are intermediate between nifedipine and verapamil. Diltiazem exerts minimal cardiodepressant effects and is less likely to potentiate beta blockers.

MAGNESIUM SULPHATE

Magnesium regulates intracellular calcium and potassium levels by activation of membrane pumps and competition with calcium for transmembrane channels. Physiological effects are widespread, affecting cardiovascular, central and peripheral nervous systems and the musculoskeletal junction.[12]

It acts as a direct arteriolar and venous vasodilator causing reductions in blood pressure. Modulation of centrally mediated and peripheral sympathetic tone results in variable effects on cardiac output and heart rate.

Consequently, it has an established role in the treatment of pre-eclampsia and eclampsia,[13] perioperative management of phaeochromocytoma[14] and treatment of autonomic dysfunction in tetanus.[15] It has been proposed as a possible agent for the prevention of secondary ischaemia after aneurysmal subarachnoid haemorrhage; however, evidence of a benefit on outcome is still lacking.[16]

DIRECT-ACTING VASODILATORS

These drugs act directly on vascular smooth muscle and exert their effects predominantly by increasing the concentration of endothelial nitric oxide. These drugs are also known as nitrovasodilators.[17]

SODIUM NITROPRUSSIDE

Sodium nitroprusside is a non-selective vasodilator that causes relaxation of arterial and venous smooth muscle. It is compromised of a ferrous ion centre associated with five cyanide moieties and a nitrosyl group. The molecule is 44% cyanide by weight.

It is reconstituted from a powdered form. The solution is light sensitive so it requires protection from exposure to light (e.g. by wrapping administration sets in aluminium foil). Prolonged exposure to light may be associated with an increase in release of hydrogen cyanide, although this is seldom clinically significant.

When infused intravenously, sodium nitroprusside interacts with oxyhaemoglobin, dissociating immediately to form methaemoglobin while releasing free cyanide and nitric oxide. The latter is responsible for the vasodilatory effect of sodium nitroprusside.

Dosage is from 0.5 μg/kg/min to 8 μg/kg/min, but should always start at a low infusion rate and build up slowly.

Onset of action is almost immediate with a transient duration, requiring continuous intravenous infusion to maintain a therapeutic effect. Tachyphylaxis can occur and large doses should not be used if the desired

therapeutic effect is not attained, as this may be associated with toxicity.

Sodium nitroprusside produces direct venous and arterial vasodilatation, resulting in a prompt decrease in systemic blood pressure. The effect on cardiac output is variable. Decreases in right atrial pressure reflect pooling of blood in the venous system, which may decrease cardiac output. This may result in reflex tachycardia that may oppose the overall reduction in blood pressure. In patients with left ventricular failure, the effect on cardiac output will depend on initial left ventricular end-diastolic pressure.

Sodium nitroprusside may potentially increase myocardial ischaemia in patients with coronary artery disease by causing an intracoronary steal of blood flow away from ischaemic areas by arteriolar vasodilatation. Secondary tachycardia may also exacerbate myocardial ischaemia.

Due to its non-selectivity, sodium nitroprusside has direct effects on most vascular beds. In the cerebral circulation, sodium nitroprusside is a cerebral vasodilator, leading to increases in cerebral blood flow and blood volume. This may be critical in patients with increased intracranial pressure. Rapid and profound reductions in mean arterial pressure produced by sodium nitroprusside may exceed the autoregulatory capacity of the brain to maintain adequate cerebral blood flow.

Sodium nitroprusside is a pulmonary vasodilator and may attenuate hypoxic pulmonary vasoconstriction, resulting in increased intrapulmonary shunting and decreased arterial oxygen tension. This phenomenon may be exacerbated by associated hypotension.

The prolonged use of large doses of sodium nitroprusside may be associated with toxicity related to the production and cyanide and, to a lesser extent, methaemoglobin.[18]

Free cyanide produced by the dissociation of sodium nitroprusside reacts with methaemoglobin to form cyanmethaemoglobin, or is metabolised by rhodenase in the liver and kidneys to form thiocyanate. A healthy adult can eliminate cyanide at a rate equivalent to a sodium nitroprusside infusion of 2 μg/kg per min or up to 10 μg/kg per min for 10 minutes, although there is marked inter-individual variability.

Toxicity should be of concern in patients who become resistant to sodium nitroprusside despite maximum infusion rates and who develop an unexplained lactic acidosis. In high doses, cyanide may cause seizures.

Treatment of suspected cyanide toxicity is cessation of the infusion and administration of 100% oxygen. Sodium thiosulphate (150 mg/kg) converts cyanide to thiocyanate, which is excreted renally. For severe cyanide toxicity, sodium nitrite may be infused (5 mg/kg) to produce methaemoglobin and subsequently cyanmethaemoglobin. Hydroxycobalamin, which binds cyanide to produce cyanocobalamin, may also be administered (5 g over 15 minutes, which may be repeated in severe cases).

GLYCERYL TRINITRATE

Glyceryl trinitrate is an organic nitrate that generates nitric oxide through a different mechanism from sodium nitroprusside.

The pharmacokinetics allows glyceryl trinitrate to be given by infusion, with a longer onset and duration of action than sodium nitroprusside. The intravenous dosage can start at 5 μg/min and increase incrementally to 200 μg/min (max dose 400 μg /min). Glyceryl trinitrate may also be administered sublingually, orally or transdermally.

Tachyphylaxis is common with glyceryl trinitrate; doses should not be increased if patients no longer respond to standard doses. Glass bottles or polyethylene administration sets are required as glyceryl trinitrate is absorbed into standard polyvinylchloride sets.

The effects on the peripheral vasculature are dose-dependent, acting principally on venous capacitance vessels to produce venous pooling and decreased ventricular preload. Together with furosemide, glyceryl trinitrate is particularly useful in treating acute cardiac failure and pulmonary oedema.

Glyceryl trinitrate primarily dilates larger conductance vessels of the coronary circulation, resulting in increased coronary blood flow to ischaemic subendocardial areas, thereby relieving angina pectoris. This is in contrast to sodium nitroprusside, which may cause a coronary steal phenomenon.

Reductions in blood pressure are more dependent on blood volume than with sodium nitroprusside. Precipitous falls in blood pressure may occur in hypovolaemic patients with small doses of glyceryl trinitrate. In euvolaemic patients, reflex tachycardia is not as pronounced as with sodium nitroprusside. At higher doses, arteriolar vasodilatation occurs without significant changes in calculated systemic vascular resistance. More recently glyceryl trinitrate has been suggested as one approach to improve microcirculatory flow in septic shock, but only after adequate fluid resuscitation.[19]

Glyceryl trinitrate is a cerebral vasodilator and should be used with caution in patients with known or suspected raised intracranial pressure. Headache due to this mechanism is a common side-effect in conscious patients.

ISOSORBIDE DINITRATE

Isosorbide dinitrate is the most commonly administered oral nitrate for the prophylaxis of angina pectoris. It has a physiological effect that lasts up to 6 hours in doses of 60–120 mg. The mechanism of action is the same as glyceryl trinitrate. Hypotension may follow acute administration, but tolerance to this develops with chronic therapy.[20]

HYDRALAZINE

Hydralazine is a potent, arterioselective, direct-acting vasodilator that acts via stimulation of cGMP and inhibition of smooth muscle myosin light chain kinase.

Following intravenous administration, 5–10 mg intravenously, hydralazine has a rapid onset of action, usually within 5–10 minutes. It can alternatively be given by continuous intravenous infusion, initially 200–300 μg/min and maintenance usually 50–150 μg/min, and may also be administered orally. The drug is partially metabolised by acetylation, for which there is marked inter-individual variability (35% of the population are slow acetylators). Although this does not have much clinical significance regarding the antihypertensive effects, it is important with respect to toxicity.[20]

Hydralazine causes predominantly arteriolar vasodilatation that is widespread but not uniform. It is associated with direct and reflex sympathetic activity, so that cardiac output and heart rate are increased. Prolonged use of hydralazine stimulates renin release and is associated with sodium and water retention. Consequently, hydralazine is frequently administered with beta blockers and/or diuretics.

Chronic use of hydralazine may be associated with immunological side-effects including lupus syndrome, vasculitis, haemolytic anaemia and rapidly progressive glomerulonephritis.

ALPHA-ADRENERGIC ANTAGONISTS

Several groups of compounds act as alpha-adrenergic blockers with variable affinity for populations of α-receptors. Physiology and pathophysiology may influence the responsiveness of the drug receptor–effector relationship. Receptor pathobiology is discussed in Chapter 90. Consequently, there may be marked inter- and intra-individual variability in the patient's response to these drugs.

There are six main groups of α-receptor antagonists: imidazolines (e.g. phentolamine), haloalkylamines (e.g. phenoxybenzamine), prazosin, beta-adrenergic antagonists with a receptor antagonism (labetalol, carvedilol), phenothiazines (chlorpromazine) and butyrophenones (haloperidol).

PHENTOLAMINE

Phentolamine is a non-selective, competitive antagonist at α_1- and α_2-receptors. At low doses, phentolamine causes prejunctional inhibition of norepinephrine (noradrenaline) release (via α_2-receptor inhibition). At higher doses, more complete α-receptor blockade is achieved, with enhancement of effects of beta agonists due to increased local concentration of norepinephrine produced by α_2-blockade (see Ch. 90, Fig. 90.3a).

Phentolamine is administered intravenously and may be given intermittently or by infusion. Onset is rapid (within 2 minutes), with a duration of action of 10–15 minutes.

Arteriolar and venous vasodilatation reduces systemic blood pressure. Effects on cardiac output are variable, and there is modest reflex sympathetic stimulation without significant increases in heart rate.

PHENOXYBENZAMINE

Phenoxybenzamine is a non-selective, non-competitive, α_1- and α_2-receptor antagonist. Blockade is also produced on histamine, serotonin and acetylcholine muscarinic receptors. Reuptake of norepinephrine is blocked, thereby potentiating the effects of beta agonists.

Phenoxybenzamine is usually administered orally, but may also be given intravenously (taking care to avoid extravasation as it is irritant to tissues). It has a long onset of action and prolonged duration of action (3–4 days). It causes a gradual reduction in systemic blood pressure, without rapid reflex sympathetic activity.

Prolonged use is associated with increased beta-adrenergic effects, predominantly increased heart rate, for which combination therapy with beta blockade is used. Phenoxybenzamine is primarily used in the management of phaeochromocytoma, either preoperatively or long term in inoperable patients. It may also be used to control autonomic hyperreflexia in patients with spinal cord transection.[21]

PRAZOSIN

Prazosin is a relatively arterioselective, competitive, α_1-receptor antagonist. It acts postjunctionally and therefore does not inhibit reuptake of norepinephrine. Consequently, it produces less tachycardia for a given reduction in systemic blood pressure.

It is administered orally and usually used for essential or renovascular (hyperreninaemia) hypertension. It is frequently used in combination with beta blockers and diuretics, particularly in patients with renal dysfunction.

LABETALOL

Labetalol is specific competitive antagonist at α_1-, β_1- and β_2-adrenergic receptors. Beta blockade effects predominate, with a approximate ratio of α_1 : β-receptor blockade of 1 : 4–7. Labetalol has partial agonist effects on β_2-receptors.

It is administered intravenously (typically 10–50 mg), has a rapid onset of action (5–10 minutes) with a duration of 2–6 hours. It may be given by infusion (usually 15–180 mg/h).

Systemic blood pressure and cardiac output are reduced by a combination of negative inotropy, arterial and venous vasodilatation. Reflex tachycardia

is attenuated by beta blockade. These properties make labetalol particularly useful in controlled hypotension during anaesthesia and surgery to reduce bleeding.

Side-effects such as bronchospasm and hyperkalaemia relate predominantly to beta blockade.

CARVEDILOL

Carvedilol is a non-selective beta blocker with α_1-antagonist activity. Most of the vasodilator activity relates to α_1-antagonism, although at high concentrations it also blocks calcium entry. The ratio of $\alpha_1 : \beta$-receptor blockade is 1 : 10.

It is administered orally; no intravenous preparation is available.

Recent studies have demonstrated slowing of progression of congestive cardiac failure and improved mortality, particularly when used in conjunction with ACE inhibitors in patients with mild to moderate cardiac failure.[22,23] It may also be used in patients who cannot be treated with ACE inhibitors.

HALOPERIDOL AND CHLORPROMAZINE

These drugs act as competitive α-receptor antagonists causing non-selective vasodilatation and blockade of norepinephrine reuptake.

These drugs are primarily used as major tranquillisers or antipsychotics; their effect on the peripheral vasculature should be regarded as a side-effect, rather than a specific therapeutic action.

Reduction of systemic blood pressure is variable and may be precipitous, particularly in hypovolaemic patients with high sympathetic drive. These drugs may be useful in neurogenic hypertension, and are not regarded as first-line vasodilators.

INODILATORS

Many inotropic drugs have peripheral vascular effects and these are discussed in more detail in Chapter 90.

At low doses, epinephrine, norepinephrine and dopamine are predominantly beta agonists and cause both arterial and venous vasodilatation, which may cause reductions in mean arterial pressure.

Dobutamine and isoprenaline are predominantly beta agonists and may cause decreases in mean arterial pressure, particularly in hypovolaemic patients or those with increased sympathetic drive. These agents may have a role in reducing left ventricular afterload in patients with systolic heart failure.

Milrinone is a selective type III phosphodiesterase inhibitor that prevents the breakdown of cAMP within cardiac and vascular tissues. The increased cAMP levels lead to increased levels of intracellular calcium and thus increased contraction of cardiac muscle. Within vascular smooth muscle the cAMP inhibits myosin light chain kinase producing less contraction and thus vascular relaxation.

Levosimendan is a newer calcium sensitiser that leads to a greater ventricular contraction for the same intracellular calcium concentration. It also leads to vasodilatation, mediated by activation of ATP-sensitive sarcolemmal and mitochondrial potassium channels. The drug itself has a relatively short half-life, but it has a long-acting active metabolite so that haemodynamic effects may be maintained for up to 7 days.

Both milrinone and levosimendan can lead to marked hypotension, particularly if a bolus dose is given. Therefore in critically ill patients a loading dose is best avoided and any excessive vasodilation may need to be balanced by a low dose of a vasoconstrictor. Usual infusion rates of milrinone are 0.375–0.75 μg/kg/min and levosimendan 0.05–0.2 μg/kg/min.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibition has become a cornerstone in the management of patients with hypertension, cardiac failure and ischaemic heart disease.[24,25] They are now recommended as first-stage treatment for hypertension in Caucasian patients <55 years and patients with diabetic nephropathy.[7] These drugs act by non-selective, competitive, irreversible inhibition to the angiotensin I binding site thus reducing conversion to angiotensin II.

There are a very large number of ACE inhibitors on the market with very high penetration into the ambulant patient population. These drugs are administered orally; there are no routinely used parenteral preparations. Consequently, many critically ill patients admitted to the ICU may be taking ACE inhibitors. As a general rule, ACE inhibitors are stopped in most critically ill patients until vital organ (specifically renal) function is stabilised and the patient can take them enterally. Thereafter, doses are gradually increased over time with close monitoring of renal function.

PREPARATIONS

Captopril has a short half-life and therefore may be useful for initiating treatment within the ICU. It is administered orally in increasing doses and intervals to a maximum dose of 50 mg 8-hourly. It may be administered sublingually in acute hypertension (5–25 mg), with an onset of action in 20–30 minutes, and duration of 4 hours. There are no significant differences in the cardiovascular effects between captopril and other preparations.

Enalapril is a prodrug, effective by hepatic metabolism to enalaprilat, producing a slower and more controlled action. It is administered orally in 5 mg increments to a total of 20 mg twice daily.

Lisinopril has the advantage of single daily dosing and may be useful in stable critically ill patients.

CARDIOVASCULAR EFFECTS

The cardiovascular effects of ACE inhibition are widespread, with effects that influence the peripheral vasculature, cardiac performance, and salt and water homeostasis. Consequently, ACE inhibitors are not principally regarded as vasodilators, although they have both direct and indirect effects on the peripheral vasculature.

Increased production of endothelial vasodilators such as prostacyclin and decreased production of endothelin by angiotensin result in generalised venous and arteriolar vasodilatation. This occurs in the absence of reflex sympathetic activity or changes in heart rate, due to the modulation of adrenergic stimulation. Systemic blood pressure is reduced without changes in cardiac output or heart rate.

ACE inhibition is associated with improved myocardial performance following acute myocardial infarction due to left ventricular remodelling and improvement in neurohumoral activation. These drugs have been shown to improve survival following myocardial infarction in patients with left ventricular dysfunction.[26]

'First-dose hypotension' is described in patients receiving ACE inhibitors for the first time. This may occur particularly in patients who are salt- and water-depleted, or those who develop sensitivity to the drug. Drug sensitivity may also present as a sudden decrease in renal function following commencement of the drug (see below).

RENOVASCULAR EFFECTS

ACE inhibitors may cause renal failure, particularly in patients with renovascular disease, hyperreninaemic hypertension and acute kidney injury. The renal effects of ACE inhibitors may be potentiated by diuretics, non-steroidal anti-inflammatory drugs and beta blockers. ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis.

As a rule in intensive care patients, ACE inhibitors are started in suitable patients once renal function has stabilised and the patient no longer requires inotropic support. Initial doses should be low and increased as tolerated.

SIDE-EFFECTS AND TOXICITY

In addition to renal dysfunction, ACE inhibitors may be associated with a number of side-effects. The most common of these is cough, which is due to the increased production of kinins.[27]

Severe angioneurotic oedema causing upper-airway obstruction may occur with all ACE inhibitors, although this is less common with enalapril and lisinopril. This is due to increased activation of bradykinins. ACE inhibitors are contraindicated in patients with a history of hereditary or idiopathic angioneurotic oedema[28] and should be avoided in pregnancy.

Neutropenia and agranulocytosis are uncommon but potentially lethal side-effects in susceptible patients.

ANGIOTENSIN RECEPTOR BLOCKERS

These are a newer class of antihypertensive drugs that cause irreversible, selective blockade of angiotensin II at AT_1 receptors.[29,30]

Losartan is the prototype, which has been followed by newer compounds such as irbesartan, valsartan and telmisartan. These drugs are oral preparations; there is no parenteral form.

The cardiovascular profile of angiotensin receptor blockers is similar to the ACE inhibitors, but selective blockade of angiotensin II offers several possible advantages over ACE inhibitors. These drugs are long-acting and may be given once daily; onset of action is slow, thereby avoiding first-dose hypotension; side-effects such as cough and angioneurotic oedema are less common.[31] Angiotensin receptor blockers may be used as an alternative to ACE inhibitors but they should not be combined.[7]

CENTRALLY ACTING AGENTS

These agents modulate adrenergic stimulation at central nervous system and spinal cord level. The vasomotor centre of the medulla mainly controls sympathetic pressor influences, although other brainstem, midbrain and spinal centres have a role.

Most central responses are mediated through α_2-adrenergic receptors, which modulate the release and reuptake of norepinephrine, with subsequent effects on the peripheral vasculature and cardiac function.

CLONIDINE

Clonidine is a centrally acting α_2-agonist that stimulates inhibitory neurons in the vasomotor centre. This results in a reduction in sympathetic outflow from the central nervous system and is associated with negative inotropy and reduction in heart rate. Systemic blood pressure is reduced by this mechanism, with associated arteriolar and venous vasodilatation. Clonidine has centrally acting analgesic properties, which make it a suitable drug in patients with postoperative hypertension.

Peripherally, it stimulates prejunctional α_2-receptors, thereby decreasing norepinephrine release, but may also have an effect at postjunctional α_1-receptors, causing vasoconstriction. This may present as rebound hypertension following initial reduction of blood pressure, as there is variable duration of the central and peripheral effects.

Clonidine can be administered orally (50–100 μg 8-hourly) or by intravenous injection (25–150 μg) or by infusion (maximum 750 μg in 24 hours). It has a rapid onset of action (5–10 minutes) and duration of action of 20–30 minutes.

METHYLDOPA

Methyldopa acts as a centrally acting 'false' transmitter following metabolism to methylnorepinephrine and subsequent stimulation of α_2-receptors leading to reduced sympathetic outflow, although the precise mechanism is not clear.

It has a limited role in hypertensive emergencies, but is useful in accelerated essential, renovascular and pregnancy-induced hypertension.

It is administered orally in doses of 250 mg to 3 g per day although side-effects (abnormal function, depression) may be minimised if the daily dose is <1 g. It may lead to a positive direct Coombs test in 20% of patients.

OTHER ANTIHYPERTENSIVE AGENTS

BETA-ADRENERGIC ANTAGONISTS

Beta blockers have been used for the treatment of hypertension for over 30 years and have an increasingly important role in the management of cardiac failure.[32–34] Although no longer recommended as first-step treatment of hypertension they may be used if ACE inhibitors are poorly tolerated.[7]

In addition to decreasing heart rate and contractility, beta blockers have other neurohumoral effects that affect vascular tone. These relate to inhibition of renin release from juxtaglomerular cells (see Fig. 91.1) and prejunctional inhibition of norepinephrine that result in reduction in vascular tone and blood pressure. A central effect of beta blockers has also been proposed.

The mode of action has been described in terms of selectivity to blockade of beta-adrenergic receptors (β_1 and/or β_2). While this is an appropriate pharmacological distinction, the clinical activity of these drugs is not as predictable due to mixed populations of β_1- and β_2-receptors in most organs and variable receptor responsiveness in physiological and pathophysiological conditions. Consequently, there is marked inter-individual variability in the response to these drugs. In high-enough doses, whether intentionally or due to toxicity, all beta blockers will cause generalised antagonism with resultant therapeutic and toxic effects.

Lipid-soluble beta blockers include propranolol and metoprolol, which are predominantly excreted by the liver; atenolol and sotalol are water-soluble and predominantly renally excreted, warranting caution with these drugs in patients with renal dysfunction.

Beta blockers may be given orally or intravenously. As there is significant first-pass metabolism, doses for oral and intravenous administration are markedly different.

Esmolol is an intravenous beta blocker that is rapidly metabolised by red cell esterases and is therefore not dependent on renal or hepatic function. Its rapid onset of action and short duration allow infusion of drug, making it a useful drug in patients with acute hypertensive states associated with tachycardia. Labetalol and carvedilol are discussed above.

Beta blockers are frequently used as adjuncts to vasodilators in the treatment of hypertensive emergencies and states, particularly where reflex tachycardia and sympathetic stimulation occur (e.g. hydralazine, nifedipine and prazosin).

Side-effects and toxicity of beta blockers include bradycardia (which may be profound), hypotension, bronchoconstriction (caution in patients who have asthma), aggravation of peripheral vascular ischaemia, hyperkalaemia and masking of the sympathetic response to hypoglycaemia.

DIURETICS

As with beta blockers, diuretics have an established place in the management of hypertension. In addition to their effects on salt and water excretion and inhibition of aldosterone, direct vasodilatory effects are associated with diuretics such as furosemide and the thiazides.

These drugs have a rapid venodilatory action, which may be due to inhibition of norepinephrine-activated chloride channels on veins. Reductions of blood pressure and right atrial pressure may occur following low doses, and may present before an associated diuresis.

All diuretics should be used with caution in patients with renal dysfunction and avoided if hypovolaemia is present or suspected.

PULMONARY VASODILATORS

Pulmonary vasodilators may be used in the ICU mainly to treat acute right-sided heart failure commonly after cardiac surgery/transplantation. Many of the systemic vasodilators detailed above (namely calcium channel blockers, sodium nitroprusside and nitrates) will also have vasodilatory effects within the pulmonary circulation. Specific pulmonary vasodilators may be inhaled or administered intravenously.

NITRIC OXIDE

As detailed above, nitric oxide (NO) is an endogenous vasodilator. When inhaled it leads to vasodilation in only the ventilated areas of the lung, and rapid combination with haemoglobin prevents systemic vasodilation. This may improve ventilation–perfusion mismatch resulting in an improved oxygenation but controlled trials have not demonstrated any beneficial effect on outcomes in severe acute lung injury and it may have an adverse effect on kidney function.[35] Its use is

now mainly confined to treatment of acute pulmonary hypertension post cardiac surgery.

NO is oxidated to NO_2 particularly in a high-oxygen environment and therefore NO_2 levels should be carefully monitored. Similarly appropriate scavenging systems must be employed.

Rebound pulmonary hypertension may occur and so NO therapy should be slowly weaned rather than abruptly stopped.

PROSTACYCLIN

Inhaled epoprostenol or iloprost (a prostacyclin derivative) can be used as alternatives to NO. Care should be taken to avoid systemic hypotension.

SILDENAFIL

Sildenafil is a phosphodiesterase type 5 inhibitor used in the management of chronic pulmonary hypertension, as well as erectile dysfunction. There are reports of its use for acute pulmonary hypertension within the ICU and that it can improve haemodynamics, however, by increasing shunt fraction it might worsen oxygenation when used in acute lung injury.[36]

DRUG SELECTION

The clinical use of vasodilators in intensive care is different from their use in ambulatory patients. In the critically ill patient, these drugs are primarily used to control acute rises in mean arterial pressure associated with sympathetic stimulation, or as specific treatment of hypertensive emergencies.[37]

The ideal vasodilator is therefore one that has a rapid and predictable onset of action, allows titration to achieve a desired systemic blood pressure, does not compromise cardiac output, does not cause significant reflex tachycardia and is non-toxic.

The selection of drug to treat hypertensive states will depend on the predominant cause of hypertension and the mechanism of action in the homeostatic pathway (outlined in Fig. 91.1).

There are no large studies investigating optimum therapy in patients presenting with hypertensive emergencies. These conditions occur in a heterogeneous group of patients and drug selection is essentially determined by the underlying pathophysiology, personal preference and experience.[37]

MONITORING

The principles of haemodynamic monitoring in patients receiving vasoactive drugs are outlined in Chapter 90.

Patients with severe hypertension or those receiving infusions or doses of potent vasodilators such as sodium nitroprusside and glyceryl trinitrate must be monitored via an intra-arterial catheter. Non-invasive measurement devices are not rapid or accurate enough and are not recommended in patients with hypertensive emergencies.

As peripheral vasodilators have significant effects on both the arterial and venous systems, assessment of volume status is important. In the majority of patients, establishing a euvolaemic state is essential before commencing a vasodilator.

DOSAGES AND DRUG ADMINISTRATION

Vasodilators administered via infusion are delivered through a dedicated central venous catheter using infusion pumps or syringe drivers and titrated to achieve a target mean arterial pressure. Infusion lines should be free of injection portals and clearly marked with identifying labels. Common drug doses are shown in **Table 91.1**.

SPECIFIC SITUATIONS

The following is a summary of the clinical uses of the above drugs in hypertensive states commonly encountered in the ICU. Specific pharmacology and physiological effects are discussed above.

ACUTE HYPERTENSION

The most common cause of hypertension in intensive care patients is pain or agitation, particularly in postoperative patients. It is important that patients have adequate analgesia and sedation before antihypertensives or vasodilators are used. Other common causes of hypertension include hypothermia, urinary retention, positional discomfort and omission of pre-admission antihypertensives, particularly beta blockers. The majority of instances of acute hypertension in the ICU will respond to simple measures addressing the above.[38]

Sustained hypertension may be treated acutely with incremental doses or infusions of short-acting drugs such as glyceryl trinitrate, sodium nitroprusside, labetalol, hydralazine, nifedipine or clonidine. Infusions of vasodilators may be required if hypertension persists, or if the patient in unable to take longer-acting oral agents such as prazosin or amlodipine. Hypertension associated with tachycardia may be treated with beta blockers.

HYPERTENSIVE ENCEPHALOPATHY

Hypertensive encephalopathy is defined as an acute organic brain syndrome occurring as a result of failure of cerebrovascular autoregulation. There may be differences in the degree of hypertension that cause encephalopathy and it may be the rate of increase of blood pressure that is more important than the absolute value. It may present as confusion, visual disturbances, blindness, seizures or stroke. Uncontrolled hypertension is

Table 91.1 Dose and infusion concentrations of commonly used vasodilators and antihypertensives in intensive care

AGENT	INFUSION/DOSE	CAUTION
Sodium nitroprusside	Diluted in 5% dextrose; range 0.5–8 µg/kg/min	Cyanide toxicity (> total dose 0.5 mg/kg per 24 hours) Photodegradation Raised intracranial pressure Rebound hypotension Shunt and oxygen desaturation
Glyceryl trinitrate	Diluted in 5% dextrose; range 5–200 µg/min	Drug binding to polyvinylchloride Tachyphylaxis Raised intracranial pressure
Hydralazine	10–20 mg i.v. bolus 20–50 mg 6–8-hourly	Tachycardia Myocardial ischaemia
Phentolamine	1–10 mg i.v. boluses 5–30 mg/h infusion	Tachycardia
Phenoxybenzamine	Oral: 10 mg/day until postural hypotension i.v.: 1 mg/kg per day	Idiosyncratic hypotension
Prazosin	2–10 mg/day, 8-hourly	
Nifedipine	5–10 mg oral/sublingual	Precipitous hypotension
Amlodipine	5–10 mg oral/day	Caution in renal impairment
Captopril	6.25–50 mg orally, 8-hourly Acute hypertension: 6.5–25 mg sublingually p.r.n.	Caution in renovascular hypertension and renal failure Pregnancy Angioneurotic oedema
Enalapril	5–20 mg/day	
Enalaprilat	0.625–5 mg bolus	Caution in renal failure and hypovolaemia
Losartan	25–100 mg/day	Caution in renal failure
Clonidine	25–150 µg i.v. bolus	Acute, perioperative centrally mediated hypertension May cause rebound hypertension with chronic use
Atenolol	1–10 mg i.v. boluses 25–100 mg oral b.d.	Caution in poor left ventricular function, asthma Hyperkalaemia Potentiated in renal failure
Metoprolol	50–100 mg 12-hourly; 5 mg i.v. bolus	As for atenolol, safe in renal failure
Esmolol	Loading dose 0.5 mg/kg 50–200 µg/kg/min infusion	
Labetalol	10–50 mg i.v. boluses 0.5–4 mg/min infusion	
Magnesium sulphate	40–60 mg/kg loading (or 6 g) 2–4 g/h infusion	Maintain serum magnesium >1.5–2 mmol/L

one of the causes of the posterior reversible encephalopathy syndrome (PRES), along with pre-eclampsia, immunosuppressant drugs and sepsis. If not adequately treated, hypertensive encephalopathy may result in intracerebral haemorrhage, coma or death.[39]

Hypertensive encephalopathy may occur in patients with untreated or undertreated hypertension or in association with other diseases such as renal disease (e.g. glomerulonephritis, renovascular disease), thrombotic thrombocytopenic purpura, immunosuppressive therapy, collagen vascular diseases or eclampsia. Consequently, drug treatment will depend on the context in which it occurs. It is also important to rule out other causes of neurological deterioration that may also

present with hypertension (e.g. stroke, intracranial haemorrhage or space-occupying lesion).

There is no evidence from randomised controlled trials to conclude one therapy is superior to another at improving outcomes. The aim of drug therapy in these patients is to reduce blood pressure in a controlled, predictable and safe way. Acutely, short-acting, titratable parenteral drugs are suitable in emergency situations. Assuming there are no absolute contraindications to beta blockers, labetalol and esmolol are ideal drugs to use. Sodium nitroprusside can be used although it may increase intracranial pressure and reduce cerebral blood flow. Phentolamine may be equally effective.[8,36]

Other agents that are useful in controlling severe hypertension include hydralazine, clonidine and ACE inhibitors (although these must be used cautiously in patients with associated renal dysfunction). Severe drops in blood pressure that might compromise end-organ perfusion have been reported after the use of nifedipine and therefore its use in the emergency setting is not recommended.[8] Combination therapy is often required, although this should be done with caution to minimise additive effects with resultant hypotension.

Patients with hypertensive emergencies are frequently hypovolaemic due to excessive sympathetic stimulation. In the absence of left ventricular failure, judicious fluid replacement may reduce blood pressure and improve renal function, thereby minimising precipitous hypotension that may result following administration of some drugs. Diuretics are generally avoided in these conditions unless there is evidence of left ventricular failure.[40]

ACUTE STROKE

Acute stroke syndromes frequently occur in the setting of severe hypertension. The reduction of mean arterial pressure must be balanced by the maintenance of adequate cerebral perfusion pressure and cerebral blood flow. Ischaemic brain is vulnerable to critical reductions in cerebral blood flow, while excessive mean arterial pressure may increase the risk of cerebral haemorrhage.[41]

Acutely, blood pressure should be maintained in a normal range until intracranial pathology has been identified by CT scan. Aggressive reduction in blood pressure is not recommended in patients with ischaemic stroke, whilst hypertension in patients with aneurysmal subarachnoid haemorrhage or intracranial haemorrhage may be managed by drugs outlined above.

AORTIC DISSECTION

Aortic dissection is the most dramatic and most rapidly fatal complication of severe hypertension. The aim of medical treatment is to control blood pressure and left ventricular ejection velocity to minimise propagation of the dissection. Blood pressure should be decreased as rapidly as possible to a normal or slightly hypotensive level. Titrations are usually made to achieve systolic blood pressures of 100–110 mmHg or mean arterial pressure of 55–65 mmHg. This will depend on the patient's premorbid blood pressure and the accuracy of blood pressure measurement. It is important to maintain blood pressure at levels compatible with adequate cerebral and renal perfusion.[42]

This is best achieved initially by use of opioid analgesia, intravenous beta blockers (e.g. esmolol, labetalol or atenolol), and possibly adding a vasodilator such as sodium nitroprusside or glyceryl trinitrate. Tachycardia must be avoided as this is a significant determinant of aortic shear force that may exacerbate the dissection. Verapamil or diltiazem are suitable alternatives for patients who have a contraindication to beta blockade.

Aortic dissection distal to the left subclavian artery is managed conservatively with antihypertensive therapy. Proximal dissections are managed surgically after acute control of blood pressure.

ACUTE MYOCARDIAL ISCHAEMIA

Myocardial ischaemia in the absence of obstructive coronary atherosclerosis may be precipitated by severe hypertension. This occurs by increased left ventricular wall stress, reduced preload, tachycardia and increased myocardial metabolic demand. Severe ischaemia may result in acute left ventricular failure.

Intravenous glyceryl trinitrate is useful in this situation and may be used in combination with beta blockers such as esmolol, labetalol or carvedilol.

ACE inhibitors may be used in the acute situation and may be required for longer-term treatment.

PHAEOCHROMOCYTOMA

Tumours of the adrenal medulla secrete catecholamines that result in initial paroxysmal, then sustained, severe hypertension. They may present to the ICU as a hypertensive emergency or perioperatively for surgical ablation.[43]

Acute hypertensive crises associated with phaeochromocytoma are managed with incremental doses or infusions of phentolamine. Untreated patients may be significantly hypovolaemic and may require judicious volume replacement. Beta blockers should not be used in the acute setting as these will potentiate unopposed alpha-adrenergic stimulation.

Phenoxybenzamine forms the mainstay of treatment and preparation for surgery. This is commenced in 20–30 mg increments and continued until blood pressure is controlled. Excessive beta-adrenergic effects are treated with beta blockers only after sufficient alpha blockade with phenoxybenzamine.[21]

Magnesium sulphate is useful in the perioperative management of phaeochromocytoma. It is given by infusion at 2–4 g/hour.[14]

RENAL FAILURE

Renal insufficiency may be a cause or consequence of a hypertensive emergency. Patients on haemodialysis (particularly those receiving erythropoietin therapy) and renal transplant patients (especially those receiving ciclosporin or corticosteroids) commonly present with severe hypertension. In patients with new-onset renal failure accompanying severe hypertension, blood pressure must be controlled without potentiating renal dysfunction. Drugs such as calcium channel blockers, phentolamine or prazosin may preserve renal blood flow and are appropriate in these patients. ACE inhibitors and diuretics should be used with caution until renal function has stabilised or improved.

Patients in the recovery phase of acute renal failure are usually hypertensive. This is a normal physiological response and should not be treated unless there is associated myocardial or cerebral ischaemia.[44]

PRE-ECLAMPSIA AND ECLAMPSIA

In addition to delivery of the baby and placenta, parenteral magnesium sulphate is the treatment of choice to prevent the evolution of pre-eclampsia to eclampsia (seizures and deteriorating encephalopathy[13]). The recommended drugs for the treatment of severe hypertension in critically ill women during pregnancy or soon after birth include labetalol, hydralazine and nifedipine.[45]

ACE inhibitors and angiotensin receptor blockers are contraindicated in pregnancy. This is discussed in Chapter 63.

DRUG INTERACTIONS

Severe rebound hypertension may result following abrupt cessation of antihypertensive treatment. Drugs associated with this discontinuation syndrome include clonidine, methyldopa, beta blockers, guanethidine and diuretics. The degree of rebound depends on the rapidity of drug withdrawal, dosage, renovascular and cardiac function. Antihypertensives should be reintroduced according to the status of the patient and the degree of hypertension managed accordingly.

Interaction with monoamine oxidase inhibitors and drugs such as indirect sympathomimetics, narcotics and tyramine-containing foods may result in a hypertensive emergency. This is best managed acutely with alpha and/or beta blockers.

Acid–base balance and disorders

Thomas J Morgan

THEORETICAL CONSIDERATIONS

Optimal enzyme action in the cell cytosol and organelles requires tight control of proton activity. Although intracellular acid–base status can be tracked using magnetic resonance imaging, this is impractical. Physicians must therefore interpret extracellular data, usually via tests on arterial blood, knowing that plasma pH exceeds intracellular pH by an average of 0.6 pH units.

WATER DISSOCIATION AND ACID–BASE

Mammals are approximately 60% water. Stewart reminded us of the central role of water in aqueous acid–base equilibria.[1,2] In simple terms, water dissociates as follows:

$$H_2O \leftrightarrow H^+ + OH^-$$

By the Law of Mass Action, at any equilibrium $[H^+][OH^-] = Kw\ [H_2O]$, where Kw is the temperature-dependent dissociation constant. The concentration of water ($[H_2O] = 55.5$ M) exceeds that of its two dissociation products by several orders of magnitude ($[H^+] = 160$ nM at 37°C). Thus water acts as a vast reservoir for protons and hydroxyl ions. Because of its numeric predominance, $[H_2O]$ can be combined with Kw to form a new constant, K′w. The equilibrium equation then simplifies to:

$$[H^+][OH^-] = K'w \qquad (92.1)$$

pH AND ACID–BASE NEUTRALITY

The negative logarithm of the proton concentration, or more exactly proton 'activity', is termed 'pH'. In aqueous solutions, neutrality occurs when $[H^+] = [OH^-]$, so that $([H^+])^2 = K'w$. Thus neutral pH = 0.5 pK′w. At 37°C, neutral pH is 6.8. Of note, this is the normal mean intracellular pH, whereas the pH of the surrounding extracellular fluid is usually >7.3, which is relatively alkaline.

THE Pa_{CO_2}/pH RELATIONSHIP IS THE ACID–BASE 'WINDOW' FOR CLINICIANS

About 15 moles of CO_2 are generated daily by aerobic metabolism. CO_2 travels from its intracellular source (P_{CO_2} > 50 mmHg (6.65 kPa)) down a series of partial pressure gradients to the atmosphere (P_{CO_2} = 0.3 mmHg (0.04 kPa)). The primary exit point is the lungs, where transit is facilitated by a large, perpetually refreshed blood–air interface. En route CO_2 equilibrates with all aqueous environments, in which the P_{CO_2} is an equilibrium value determined by regional CO_2 production, regional blood flow, alveolar perfusion and alveolar ventilation.

Clinicians use the relationship between arterial P_{CO_2} (Pa_{CO_2}) and arterial pH as their primary acid–base assessment platform. This is appropriate, because the acute Pa_{CO_2}/pH curve is a fundamental physiological property (**Fig. 92.1**). Several factors determine the shape and position of this curve.

THE Pa_{CO_2}/pH RELATIONSHIP IS DEFINED BY SEVERAL SIMULTANEOUS EQUATIONS

In all body fluids pH is a function of water dissociation modified by CO_2, other weak acids and certain electrolytes. Final equilibria obey the Laws of Mass Action, Mass Conservation, and Electrical Neutrality. In addition, non-diffusible (impermeant) ions trigger electrochemical forces known as Gibbs Donnan forces across semipermeable membranes. These influence the acid–base result.

Therefore several equations in addition to equation 92.1 must be satisfied at any equilibrium. They relate to:

1. *The interaction of carbon dioxide and water:*

   $$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

   By applying the Law of Mass Action and substituting [dissolved CO_2] for $[H_2CO_3]$, the following expression is derived:

   $$pH = 6.1 + \log_{10}([HCO_3^-]/\alpha P_{CO_2}) \qquad (92.2)$$

   This is the Henderson–Hasselbalch equation, where α is the plasma CO_2 solubility coefficient (0.03), and 6.1 is the pKa, the negative logarithm of the dissociation constant.
2. *Bicarbonate dissociation:* carbonate is present in micromolar concentrations only:

   $$[H^+][CO_3^{2-}] = Keq\,[HCO_3^-] \qquad (92.3)$$

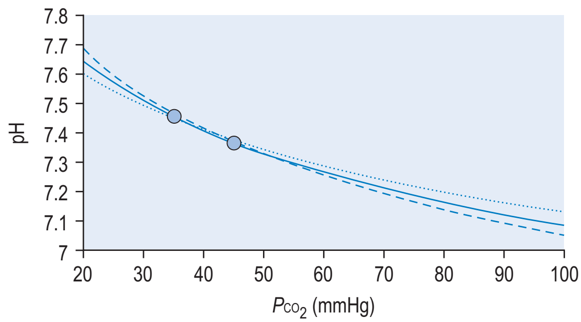

Figure 92.1 P_{CO_2}/pH relationships. The solid line shows the normal in vivo Pa_{CO_2}/pH relationship. The normal Pa_{CO_2} range is between the filled circles. To the left of the circles there is an increasing acute respiratory alkalosis, and to the right an increasing acute respiratory acidosis. The interrupted curve represents the normal in vitro whole-blood relationship, and the dotted curve is the same relationship for separated plasma. A point of commonality exists at P_{CO_2}=40 mmHg (5.32 kPa).

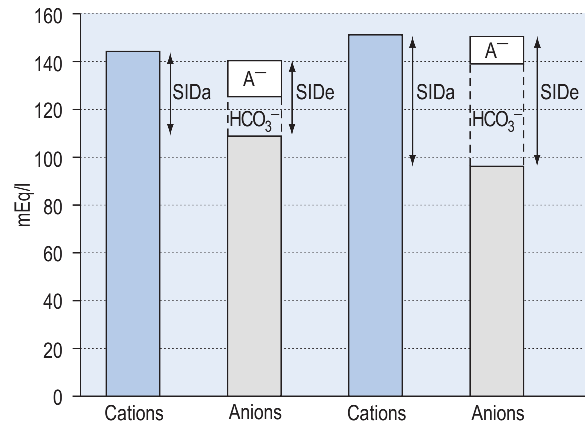

Figure 92.2 Gamblegrams of plasma strong and weak ions (in vitro data from CO_2 equilibrated normal blood). On the left, P_{CO_2}<20 mmHg (2.66 kPa). On the right, the same blood with P_{CO_2}>200 mmHg (26.6 kPa). The transition from hypocapnia to hypercapnia increases SIDa, with ionic redistribution between red cells and plasma due to altered Gibbs Donnan forces. There are almost identical increases in SIDe ($[A^-]+[HCO_3^-]$), also known as 'buffer base', although $[A^-]$ actually falls. Note that the SIG, which is SIDa–SIDe, remains close to zero.

3. *Non-volatile weak acid dissociation:* fluid compartments have varying concentrations of non-volatile (non-CO_2-generating) molecules possessing weak acid properties. Like all weak acids the overall negative charge of these molecules alters with pH. In plasma, they consist mainly of albumin and inorganic phosphate. In red cells haemoglobin predominates. Interstitial fluid contains much smaller concentrations, primarily phosphate. For convenience Stewart modelled all non-volatile weak acids as having a single anionic form (A^-) and a single conjugate base form (HA).

$$HA \leftrightarrow H^+ + A^-$$

By applying the Law of Mass Action:

$$[H^+][A^-] = KeqHA \qquad (92.4)$$

4. *The Law of Mass Conservation:* Stewart termed the total concentration of non-volatile weak acids in any compartment 'A_{tot}', where:

$$A_{tot} = [HA] + [A^-] \qquad (92.5)$$

A_{tot} is an imposed mass constant. It does not vary with pH. A pH change merely shifts the balance between HA and A^-.

5. *The Law of Electrical Neutrality:* linked to Stewart's concept of strong ion difference.[1,2] Certain elements in body fluids such as Na^+, K^+, Ca^{2+}, Mg^{2+} and Cl^- exist as completely ionised entities. At physiological pH they include anions with pKa values ≤4, for example sulphate, lactate and beta-hydroxybutyrate. Stewart described these compounds as 'strong ions'. In body fluids there is a surfeit of strong cations, which he referred to as the 'strong ion difference' (SID). In other words, SID=[strong cations]−[strong anions]. Being a 'charge' space, SID is expressed in mEq/L. SID calculated from measured strong ions in normal plasma is 42 mEq/L.

Hence, by the Law of Electrical Neutrality:

$$SID + [H^+] - [HCO_3^-] - [CO_3^{2-}] - [A^-] - [OH^-] = 0 \qquad (92.6)$$

6. *Gibbs Donnan forces:* impermeant ions influence equilibria across semipermeable membranes, causing redistribution of permeant ions to balance electrical and concentration gradients. The plasma compartment (volume 3 L), erythrocyte compartment (volume 2 L) and interstitial space (volume 13.5 L) contain different concentrations of impermeant anions, mainly albumin or haemoglobin. The highest concentration occurs within erythrocytes, in which negatively charged haemoglobin molecules attract diffusible cations (such as Na^+, K^+) from the adjacent plasma compartment while repelling diffusible anions (primarily Cl^-). To prevent cell swelling and haemolysis sodium, potassium and other cations are continually redistributed against the Donnan forces by energy-dependent transmembrane pumps. Importantly chloride, the major anion, remains susceptible to Donnan effects.

Because there are differing compartmental concentrations of impermeant weak acids a pH change causes differential charge alterations driving further redistributions, mainly chloride, between compartments. The net effect is that plasma SID goes up and down with Pa_{CO_2} (**Fig. 92.2**), the origin of the so-called Hamburger

effect. Ionic shifts appear largely confined within the contiguous space occupied by the interstitial fluid (I), plasma (P) and erythrocytes (E) (the IPE space).[3] In other words SID_{IPE} does not alter with P_{CO_2}, a phenomenon underpinning the CO_2 – invariance of standard base excess – see below.

At equilibrium, equations 92.1 to 92.6 plus the Donnan equilibria must be satisfied. In the Stewart physical chemical model,[2] direct manipulation of pH, HCO_3^-, CO_3^{2-}, A^- and OH^- is impossible. Their values can be altered only indirectly via three independent variables imposed on but not controlled by the system. These are Pa_{CO_2}, which is externally regulated by alveolar ventilation, SID (more precisely SID_{IPE}, immune to Gibbs Donnan forces) and A_{totIPE}.

Thus for any individual the Pa_{CO_2}/pH relationship is a unique acid–base 'signature' (see Fig. 92.1), and ultimately a complex function of SID_{IPE} and A_{totIPE}. This aspect of the Stewart approach and its implications are disputed.[4]

WEAK IONS AND BUFFER BASE

SID is a charge space occupied by weak ions including H^+, OH^-, HCO_3^-, CO_3^{2-} and A^- arising from variably dissociating conjugate bases. Their total net charge must equal the inverse of SID. However, HCO_3^- and A^- numerically occupy the entire space (see Fig. 92.2). Other ions are in minute concentrations, either micromoles/L or with protons, nanomoles/L. SID therefore dictates the buffer base concentration and is numerically identical to it, so that $SID = [HCO_3^-] + [A^-]$. With Figge's linear approximations for A^-.[5] this allows us to reduce Stewart's equations from six to three without sacrificing accuracy.[6]

$$[A^-] = [Alb] \times (0.123 \times pH - 0.631) + [Pi] \times (0.309 \times pH - 0.469)$$

$$[HCO_3^-] = 0.0301 \times P_{CO_2} \times 10^{(pH-6.1)}$$

$$SIDe = [HCO_3^-] + [A^-]$$

[Alb] is albumin concentration (g/L). [Pi] is phosphate concentration (mmol/L). P_{CO_2} is in mmHg. SIDe is effective plasma SID, also known as the 'buffer base' (see Fig. 92.2).

SID calculated from measured plasma concentrations of strong ions is termed the 'apparent' SID, or SIDa (see Fig. 92.2). Disparities between SIDe and SIDa imply the presence of unmeasured ions in plasma (see below).

ISOLATED CHANGES IN SID AND A_{tot}

At any given Pa_{CO_2}, a falling SID or a rising A_{tot} reduce pH, forcing the equilibrium towards metabolic acidosis. Conversely, a rising SID or a falling A_{tot} favour a metabolic alkalosis. Some argue that SID and A_{tot} act individually. We could thus have a strong ion acidosis or

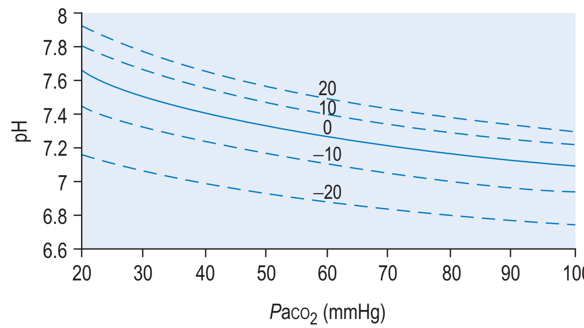

Figure 92.3 Pa_{CO_2}/pH curve shifts and associated SBE values (mEq/L). Alterations in metabolic acid–base status shift the curve down in metabolic acidosis (SBE increasingly negative) or up in metabolic alkalosis (SBE increasingly positive).

alkalosis combined with either a hyperalbuminaemic (high A_{tot}) acidosis or a hypoalbuminaemic (low A_{tot}) alkalosis.[7] However, SID and A_{tot} may be linked, with the SID set point adjusting to A_{tot}, presumably by renal chloride adjustment.[8,9]

HOW ACID–BASE DISTURBANCES AFFECT THE Pa_{CO_2}/pH RELATIONSHIP

Acute respiratory disturbances move data points along the Pa_{CO_2}/pH curve, to the left in respiratory alkalosis, and to the right in respiratory acidosis (see Fig. 92.1). In contrast, metabolic disturbances (altered extracellular SID and/or A_{tot}) shift the entire curve up or down (**Fig. 92.3**). A down-shifted curve means the pH at any given Pa_{CO_2} is lower than normal, which depending on the Pa_{CO_2} represents either a primary metabolic acidosis or else metabolic compensation for a respiratory alkalosis. With an up-shifted curve, the pH at any given Pa_{CO_2} is higher than normal, signifying a primary metabolic alkalosis or else compensation for a respiratory acidosis.

TEMPERATURE CORRECTION OF BLOOD GAS DATA – 'ALPHA-STAT' VERSUS 'pH-STAT' APPROACHES

Blood gas analysers operate at 37°C. Their software can convert pH and gas tensions to values corresponding to the patient core temperature for interpretation. This is the 'pH-stat' approach. The alternative is to act on values as measured at 37°C: the 'alpha-stat' approach. Neither approach is clearly superior.[10]

'Alpha' is the ratio of protonated to total imidazole on histidine moieties in protein molecules. At 37°C with a normal mean intracellular pH of 6.8 (neutral pH for that temperature), alpha is approximately 0.55. Maintaining alpha close to 0.55 optimises enzyme structure and function and is a fundamental goal of the alpha-stat approach.

'Alpha-stat' logic is illustrated by considering blood in a blood gas syringe placed on ice and cooled anaerobically. Several changes occur simultaneously. P_{CO_2} falls with the increasing solubility coefficient. Water dissociation is reduced with the temperature-induced decrease in K'w and the progressive hypocarbia. There is a simultaneous fall in the imidazole pKa, which is about half the fall in pK'w. The net effect at any temperature is an unaltered alpha value. On blood gas analysis the specimen is rewarmed anaerobically to 37°C. The hypocarbia resolves while K'w and the imidazole pKa regain their original values. Again there is no change in alpha.

Hence, alpha is kept at 0.55 at any patient core temperature by maintaining uncorrected Pa_{CO_2} and pH measurements in their 37°C reference ranges,[11,12] a practice that mimics the physiology of ectothermic (cold-blooded) animals. With this approach cerebral autoregulation may be better preserved.[11] Similar arguments apply in fever, the more common ICU scenario. Many intensivists follow the alpha-stat approach.

Others argue that the pH stat approach is consistent with the physiology of hibernating endothermic mammals, and that it maintains superior cerebral oxygenation and greater cerebral perfusion in induced hypothermia.[13] This was the approach during an influential trial of mild hypothermia following out-of-hospital ventricular fibrillation (VF) arrest.[14]

RENAL PARTICIPATION IN ACID–BASE

In renal failure there is a progressive metabolic acidosis. About 60 mEq of strong anions including sulphate, hippurate and others accumulate daily as metabolic end-products, reducing extracellular SID. Free water is retained, again reducing SID. Hyperphosphataemia increases A_{tot}, commonly offset in acute renal failure by coexistent hypoalbuminaemia.[15]

Traditionally, renal acid–base homeostasis is described in terms of proton excretion, filtered HCO_3^- resorption and new HCO_3^- generation. Proton excretion is facilitated by titration of urinary buffers at low urinary pH, especially the $HPO_4^{2-}/H_2PO_4^-$ system (titratable acidity), and by up-regulation of distal tubular NH_3 production to facilitate luminal proton 'trapping' as NH_4^+.[16]

From the physical chemical perspective, any analysis based on H^+ or HCO_3^- 'balances' is misleading. In the Stewart model, $[H^+]$ and $[HCO_3^-]$ balance sheets cannot apply since these are dependent variables, responsive exclusively to P_{CO_2}, SID and A_{tot}. The physical chemical explanation is simple. The kidneys regulate extracellular SID via urinary SID,[17] the principle tool being tubular NH_4^+ acting as an adjustable cationic partner for tubular Cl^- and other urinary strong anions.[18] The kidneys modify A_{tot} via phosphate excretion, which is a different concept from that of 'titratable acidity'.

ACID–BASE ASSESSMENT – THE TWO 'SCHOOLS'

By convention acid–base disorders are divided into respiratory (Pa_{CO_2}) and metabolic (non-Pa_{CO_2}). Pa_{CO_2} is the undisputed index of respiratory acid–base status. Two 'schools', Boston and Copenhagen,[19] have formed around the identification and quantification of metabolic acid–base disturbances. Both succeed as navigation systems if used correctly.

Stewart's concepts neither invalidate nor supplant the traditional approaches,[20,21] but rather help us understand their physiological basis and extend their utility.[22] SID by itself is unreliable as a measure of metabolic acid–base status. Plasma SID, the only SID directly measurable by clinicians, is subject to Donnan effects, and thus varies with Pa_{CO_2} (the only CO_2-invariant SID being SID_{IPE}).

For a pure metabolic index to succeed, it must integrate the effects of SID and A_{tot}, irrespective of the Pa_{CO_2}. The best of these is standard base excess, the flagship of the Copenhagen school. However, Boston school devotees can navigate successfully using empirical plasma bicarbonate-based 'rules of thumb' (**Table 92.1**).

BASE EXCESS AND STANDARD BASE EXCESS

In 1960 Siggaard-Andersen introduced 'base excess' (BE),[23] defined as zero when pH = 7.4 and P_{CO_2} = 40 mmHg (5.32 kPa) (both at 37°C). If pH ≠ 7.4 or P_{CO_2} ≠ 40 mmHg, BE was defined as the concentration of titratable hydrogen ion required to return the pH of ex vivo blood to 7.4 while maintaining P_{CO_2} at 40 mmHg.

In the lead-up, Astrup, Siggaard-Andersen, Engel and others equilibrated the blood of Danish volunteers with known CO_2 tensions at varying haemoglobin concentrations after adding known amounts of acid or base. The data were used to create an 'alignment nomogram' that allowed the determination of BE from simultaneous measurements of pH, P_{CO_2} and haemoglobin concentration.

Seventeen years later, Siggaard-Andersen published the Van Slyke equation.[24] It was derived from known physical chemical relationships, and superseded the empirical nomogram. The equation computes BE as $(\Delta[HCO_3^-] + \Delta[A^-])$, in other words as the deviation from normal of the buffer base concentration in whole blood (P + E). From the Stewart perspective, buffer base and SID are interchangeable terms. Hence Stewart would describe BE as the abnormality in SID_{PE} at the prevailing A_{tot}.

It became clear that BE loses CO_2 invariance in vivo, where Gibbs Donnan forces drive ionic shifts between intravascular and interstitial compartments. A change in Pa_{CO_2} forces SID_{PE} and thus BE in the opposite direction. The solution was to model the total IPE space more closely by calculating BE at a haemoglobin concentration of approximately 50 g/L.[25,26] This is standard base excess (SBE).

Table 92.1 Compensation – mechanisms and rules

DISORDER	COMPENSATION	SIMPLE RULES	BOSTON RULES
Uncompensated respiratory acidosis and alkalosis	Nil	SBE –3.0 to +3.0	Resp acidosis: $HCO_3^- = 24 + 0.1 \times (Pa_{CO_2} - 40)$ Resp alkalosis: $HCO_3^- = 24 + 0.2 \times (Pa_{CO_2} - 40)$
Compensated respiratory acidosis and alkalosis	Resp acidosis: Extracellular SID increased by decreasing urinary SID Resp alkalosis: Extracellular SID decreased by increasing urinary SID	pH is normal or $SBE = 0.4 \times (Pa_{CO_2} - 40)$	Resp acidosis: $HCO_3^- = 24 + 0.35 \times (Pa_{CO_2} - 40)$ Resp alkalosis: $HCO_3^- = 24 + 0.5 \times (Pa_{CO_2} - 40)$
Metabolic acidosis	Hyperventilation reduces Pa_{CO_2}	Pa_{CO_2} = 2 digits after decimal point of pH or $Pa_{CO_2} = 40 + SBE$ (Pa_{CO_2} rarely <10 mmHg (1.33 kPa))	$Pa_{CO_2} = 1.5 \times (HCO_3^-) + 8$
Metabolic alkalosis	Hypoventilation increases Pa_{CO_2}	Pa_{CO_2} = 2 digits after decimal point of pH or $Pa_{CO_2} = 40 + SBE$ (Pa_{CO_2} rarely >60 mmHg (7.98 kPa))	$Pa_{CO_2} = 0.9 \times (HCO_3^-) + 9$

As a metabolic acid–base index SBE is close to ideal, being both a quantitative therapeutic target and demonstrably independent of Pa_{CO_2}.[27] A useful formula is:

$$SBE = 0.93 \times ([HCO_3^-] + 14.84 \times (pH - 7.4) - 24.4)$$

with SBE and $[HCO_3^-]$ values in mEq/L. The formula can be refined to allow for variations in albumin and phosphate,[26] although the end-result is similar because haemoglobin is the predominant non-volatile weak acid in the IPE space.

A typical SBE reference range (in mEq/L) is –3.0 to +3.0. If SBE < –3.0 mEq/L, there is a down-shifted Pa_{CO_2}/pH curve. This could represent either a primary metabolic acidosis or else compensation for a primary respiratory alkalosis, depending on the Pa_{CO_2} (see below). SBE quantifies the increase in SID_{IPE} (in mEq/L) needed to return the curve to the normal position at the prevailing A_{tot} (see Fig. 92.3). In terms of the original BE definition, this is roughly the required dose of sodium bicarbonate in mmol per litre of extracellular fluid (more exactly per litre of I+P+E fluid). Similarly, if SBE > 3.0 mEq/L, there is an up-shifted curve, either a metabolic alkalosis or compensation for a respiratory acidosis. The SBE value is the decrease in SID_{IPE} needed to return the curve to the normal position at the prevailing A_{tot}. Conceptually, it approximates the dose of HCl required per litre of 'extracellular' (I+P+E) fluid. In the past SBE has been termed 'extracellular SID excess' or 'SIDex' although a more correct term would be 'SID_{IPE} excess'. A complex formalism is required to express SBE in terms of SID_P and A_{totP}.[28,29]

THE BICARBONATE-BASED APPROACH TO METABOLIC ACID–BASE – THE BOSTON 'RULES OF THUMB'

Boston 'school' devotees match the plasma $[HCO_3^-]$ against the $[HCO_3^-]$ deemed appropriate for the measured Pa_{CO_2}, using empirical 'rules of thumb' derived from clinical and experimental data (see Table 92.1).[30] An offset denotes a metabolic acid–base disturbance.

The Boston method is largely qualitative. By focusing on plasma $[HCO_3^-]$ it ignores the A^- component of the buffer base (SIDe) (see Fig. 92.2). The rules of thumb reveal whether the Pa_{CO_2}/pH curve is shifted up or down but not by how much, unlike SBE, which functions as a therapeutic target.

ACID–BASE DISORDERS – CLASSIFICATION

PRIMARY ACID–BASE DISORDERS

Primary acid–base disorders dictate the direction of the pH disturbance. They are designated by the suffix 'osis', and can be either respiratory (Pa_{CO_2}) or metabolic. Hence we can have a respiratory or metabolic acidosis or alkalosis. The final pH abnormality (if any) is designated by the suffix 'aemia'. In acidaemia, plasma pH < 7.35. In alkalaemia, plasma pH > 7.45. In opposing primary acid–base disturbances the pH can be normal.

COMPENSATION AND ITS EFFECT ON pH

Compensation is a counter-response to a primary disorder, reducing the severity of the pH disturbance. When the primary disturbance is respiratory (Pa_{CO_2}),

compensation is metabolic (renal alteration of SID and thus SBE). If the primary disturbance is metabolic (abnormal SBE), the compensation is respiratory (Pa_{CO_2}).

Metabolic compensation

In respiratory acid–base disturbances, the kidneys adjust SID_{IPE} by regulating urinary SID, primarily via urinary chloride. Sustained hypocarbia increases urinary SID causing a compensatory fall in SID_{IPE} and thus SBE. Sustained hypercarbia decreases urinary SID, increasing SID_{IPE} and thus SBE. Compensation for chronic respiratory disturbances takes time, but is ultimately effective. Over the Pa_{CO_2} range 25–80 mmHg (3.33–10.64 kPa), which encompasses most chronic respiratory disturbances, full compensation normalises the arterial pH.[27,31,32] However, this can take 5 days.

Respiratory compensation

By contrast, respiratory compensation for metabolic disturbances is faster, but less effective. A normal pH is *never* regained. Metabolic acid–base disturbances activate feedback loops linked to alveolar ventilation, forcing Pa_{CO_2} in the direction that reduces the pH perturbation. The loops are driven by CSF and plasma pH acting on the central and peripheral chemoreceptors respectively. In severe metabolic acidosis, minute ventilation can increase more than eightfold. The full response evolves over 12–24 hours, at first driven entirely by the peripheral chemoreceptors. Paradoxically the central chemoreceptors dampen the initial response, since SID equilibration between plasma and CSF is gradual, whereas P_{CO_2} equilibration is immediate.

ACID–BASE 'SCANNING TOOLS'

ELECTRICAL GAPS **(Table 92.2)**[33]

Accumulating strong anions reduce SID, causing metabolic acidosis. Other than chloride and L-lactate, strong anions are not measured routinely. However, they can be especially injurious for example in certain poisonings. Critical care practitioners use electrical 'gaps' as early warning systems.

Anion gap (AG)

The plasma AG is calculated (in mEq/L) as $[Na^+]+[K^+]-[Cl^-]-HCO_3^-]$. $[K^+]$ is omitted in many laboratories, which reduces the typical reference range to 5–15 mEq/L. The AG quantifies [unmeasured anions] − [unmeasured cations], both strong and weak. It is increased by unmeasured anions, and reduced by unmeasured cations. In health most of the AG consists of A^-, the negative charge on albumin and phosphate. The AG is altered by A_{tot} fluctuations and pH disturbances, both of which affect A^- (see Table 92.2). When used to scan for unmeasured strong anions, sensitivity and specificity are low.

Albumin-corrected anion gap (AGc)[7]

The AGc was devised to correct for variations in plasma [albumin], allocating a negative charge to

Table 92.2 Factors affecting the anion gap (AG), the albumin-corrected anion gap (AGc) and the strong ion gap (SIG)

FACTOR	AG	AGC	SIG
[Pi] ⇑	⇑	⇑	No effect

albumin appropriate for acidaemic conditions. The calculation is AG+0.25×(40−[albumin]), assuming a normal plasma [albumin] of 40 g/L. Severe alkalaemia reduces accuracy.

Strong ion gap (SIG)[33]

SIG is calculated as SIDa−SIDe, where SIDa=$[Na^+]+[K^+]+[Ca^{2+}]+[Mg^{2+}]-[Cl^-]-$[L-lactate], and SIDe=$[A^-]+[HCO_3^-]$. The unmeasured ions creating the 'gap' can be either strong or weak, but the term 'strong ion gap' has persisted. Its signal is subject to the summated variability of multiple analytes. Theoretically the SIG should be zero unless there are unmeasured ions, the list of which is smaller than with AG and AGc (Table 92.2). In many centres the normal SIG is 4 mEq/L or more, the positive bias presumably due to local variations in measurement technologies and analytic reference standards.

Other scanning tools

One refinement of the SIG, 'net unmeasured anions' (NUI), has been successfully incorporated into an acid–base diagnostic module and linked to a laboratory information system.[34] Two newer scanning tools are the 'BEua' parameter of Wolf & DeLand[25] and Anstey's 'UIX' index.[35] Both are referenced to the IPE space to quantify the unmeasured ionic component of SBE in the same dimension.[36]

THE OSMOLAL GAP

The osmolal gap scans for unmeasured osmotically active molecules. It is calculated as follows:

$$\text{osmolal gap (mOsmol/kg)} = \text{measured osmolality} - \text{calculated osmolality}$$

The formula for calculated osmolality of Bhagat and colleagues[37] is often preferred:

$$\text{calculated osmolality (mOsmol/kg)} = 1.89\,[\text{Na}] + 1.38\,[\text{K}] + 1.03\,[\text{urea}] + 1.08\,[\text{glucose}] + 7.45 \text{ (all electrolyte concentrations in mmol/L)}$$

The normal osmolal gap is <10 mosmol/kg. With an unexplained high AGc, a simultaneously raised osmolal gap suggests poisoning by methanol or ethylene glycol. However, a number of other molecules elevate the osmolal gap. These include other alcohols, mannitol and glycine, acetone and glycerol in ketoacidosis, and unknown solutes in lactic acidosis and renal failure.

PRACTICAL CONSIDERATIONS

THE DIAGNOSTIC SEQUENCE

After taking a history and examining the patient, a set of arterial blood gases should be evaluated focusing on the measured variables Pa_{CO_2} and pH. A sequence of questions can then be addressed:

Table 92.3 Acid–base status – primary survey

pH	Pa_{CO_2} (mmHg)	PRIMARY PROCESS(ES)
7.35–7.45	35–45	None
7.35–7.45	>45	1. Chronic respiratory acidosis or 2. Respiratory acidosis, metabolic alkalosis
7.35–7.45	<35	1. Chronic respiratory alkalosis 2. Respiratory alkalosis, metabolic acidosis
<7.35	<35	Metabolic acidosis
<7.35	>45	Respiratory acidosis
<7.35	35–45	Respiratory acidosis, metabolic acidosis
>7.45	>45	Metabolic alkalosis
>7.45	<35	Respiratory alkalosis
>7.45	35–45	Respiratory alkalosis, Metabolic alkalosis

WHAT IS THE PRIMARY PROCESS?

1. The primary process determines the direction of pH change.
2. Scan for primary disorders by matching the Pa_{CO_2} with the pH generated. If the direction of pH change is appropriate for the Pa_{CO_2} direction of change, there is a primary respiratory disturbance. If not, there is a primary metabolic disturbance.
3. There are nine possible combinations of Pa_{CO_2} and pH (**Table 92.3**).
4. A normal pH combined with an abnormal Pa_{CO_2} means one of two things. Either there are two opposing primary acid–base disorders, one respiratory and one metabolic, or else there is a primary respiratory acid–base disturbance with metabolic compensation. A 'normal' Pa_{CO_2} combined with an abnormal pH always represents two primary acid–base disturbances (see Tables 92.1 and 92.3).

IS THERE COMPENSATION?

1. In primary metabolic acid–base disturbances, respiratory compensation alters Pa_{CO_2} to reduce the pH disturbance. Hence there should be compensatory hypocarbia in metabolic acidosis and hypercarbia in metabolic alkalosis.
2. In primary respiratory acid–base disorders, compensation is present if the pH change is offset by an altered metabolic acid–base status. Hence in a compensated primary respiratory acidosis there should be a metabolic alkalosis (SBE>3 mEq/L), and in a compensated primary respiratory alkalosis there should be a metabolic acidosis (SBE<−3 mEq/L).

IS COMPENSATION APPROPRIATE?

1. Apply 'rules of thumb' (see Table 92.1) where applicable.
2. Remember that the pH is usually normal in fully compensated respiratory acid–base disturbances (although this can take days), whereas the pH is never normal in appropriately compensated metabolic acid–base disturbances.
3. In primary metabolic acid–base disorders, identify absent or inappropriate respiratory compensation as a separate acid–base disturbance. For example, in diabetic ketoacidosis, if the arterial pH=7.20 and the Pa_{CO_2}=20 mmHg (2.66 kPa), the patient has a metabolic acidosis with normal respiratory compensation (see Table 92.1). If, however, the pH=7.20 with a Pa_{CO_2}=32 mmHg (4.26 kPa), there is an accompanying respiratory acidosis (despite the hypocarbia). Conversely, if Pa_{CO_2}=12 mmHg (1.6 kPa) at the same pH, there is an added respiratory alkalosis.

IF METABOLIC ACIDOSIS IS PRESENT, HOW SEVERE IS IT?

1. The SBE is a quantitative index of metabolic acid–base status.
2. SBE=–4 mEq/L to –9 mEq/L indicates a mild metabolic acidosis (either primary or compensatory).
3. SBE=–10 mEq/L to –14 mEq/L indicates a moderate metabolic acidosis (either primary or compensatory).
4. SBE<–14 mEq/L indicates a severe metabolic acidosis.

IF METABOLIC ALKALOSIS IS PRESENT, HOW SEVERE IS IT?

1. SBE=+4 mEq/L to +9 mEq/L indicates a mild metabolic alkalosis (either primary or compensatory).
2. SBE=+10 mEq/L to +14 mEq/L indicates a moderate metabolic alkalosis (either primary or compensatory).
3. SBE>+14 mEq/L indicates a severe metabolic alkalosis.

WHAT IS THE AG OR PREFERABLY THE AGc?

1. If either is elevated, unmeasured anions are likely.
2. If the AGc is low or negative, suspect laboratory error, but consider lithium intoxication, IgG myeloma and others (see Table 92.2).

IS THE AGc INCREASE (IF ANY) ACCOMPANIED BY A SIMILAR REDUCTION IN SBE OR $[HCO_3^-]$?

1. An elevated AGc should be accompanied by a similar reduction in SBE or $[HCO_3^-]$. If not, there are dual disorders.
2. For example, if AGc=20 mEq/L and SBE=–15 mEq/L, there is a mixed normal AGc and raised AGc metabolic acidosis. If AGc=20 mEq/L and the SBE=0 mEq/L, there is a mixed metabolic alkalosis and raised AGc metabolic acidosis.

Box 92.1 Causes of metabolic acidosis

Normal AGc	Raised AGc
Saline infusions	L-lactate acidosis
Organic anion excretion	Ketoacidosis
Ketoacidosis	β-hydroxybutyrate, acetoacetate
Glue sniffing (hippurate, benzoate)	Renal failure
Loss high SID enteric fluid	Sulphate, hippurate, other organic anions
Small intestinal, pancreatic, biliary	Phosphate accumulation increases A_{tot}
Urinary/enteric diversions	Ethylene glycol poisoning
High urinary SID	Glycolate, oxalate
Renal tubular acidosis	Methanol poisoning
High urinary SID	Formate
Post hypocapnia	Salicylate overdose
High urinary SID	Salicylate, L-lactate, keto-anions
TPN and NH_4Cl administration	Pyroglutamic acidosis
	Pyroglutamate
	Toluene (glue sniffing)
	Hippurate, benzoate
	Short bowel syndrome
	D-lactate

IF THE AGc IS INCREASED, WHAT IS THE CAUSE?

1. There are several potential causes of a raised AGc (**Box 92.1**). Common causes include L-lactate and the ketoanions (beta-hydroxybutyrate and acetoacetate).
2. If there is no obvious cause, perform other specific assays (e.g. D-lactate, salicylate). A concurrently raised osmolal gap suggests methanol (unmeasured anion formate) or ethylene glycol toxicity (unmeasured anions glycolate and oxalate), but can also be present in ketoacidosis and hyperlactaemia. Urinary organic anions may reveal pyroglutamate.

CLINICAL ACID–BASE DISORDERS

METABOLIC ACIDOSIS

In metabolic acidosis, the SID_{IPE} is low relative to the corresponding A_{tot}. This can represent a narrowed difference between $[Na^+]$ and $[Cl^-]$ (normal AGc, Box 92.1), or an accumulation of other anions (elevated AGc, Box 92.1). Although a normal AGc acidosis is often hyperchloraemic, the absolute $[Cl^-]$ is not important, but just its value relative to $[Na^+]$.

Clinical features

Clinical features are those of acidaemia itself (Box 92.1), combined with toxicities of individual anions. These include blindness and cerebral oedema (formate), crystalluria, renal failure and hypocalcaemia (oxalate), and tinnitus, hyperventilation and fever due to uncoupling of oxidative phosphorylation (salicylate).

The adverse effects of acidaemia (**Box 92.2**) are more evident at low pH (<7.2). Acidaemia also has potential benefits. For example, the Bohr effect increases tissue oxygen availability, although rapidly counteracted by reduced 2,3-diphosphoglycerate concentrations. Lowering pH is protective in certain hypoxic stress models. During mild acidaemia therefore, the net result of harm versus benefit can be debated.

Infusion-related acidosis[38]

Large volumes of intravenous 0.9% sodium chloride cause a normal AGc metabolic acidosis. This may cause harm.[39] The SBE rarely falls below −10 mEq/L, so that with appropriate respiratory compensation the pH remains above 7.3. Cell culture and animal experiments plus low-level human evidence point to pro-inflammatory effects and other adverse consequences including hypotension, reduced renal perfusion, splanchnic dysfunction and coagulation disturbances. However, it is unclear whether hyperchloraemia rather than acidaemia is the culprit.[40]

Infusion-related acidosis is driven by the 'effective' SID of the administered crystalloid, since rapid infusion forces SID_{IPE} towards this value. The SID of administered fluid is zero whenever there are equal concentrations of the strong cation Na^+ and the strong anion Cl^-, for example in 0.9% sodium chloride, 0.45% sodium chloride and in dextrose and dextrose saline preparations. With these fluids rapid infusion will reduce extracellular SID at a rate outstripping the metabolic alkalosis of A_{tot} dilution, resulting in a metabolic acidosis.

To balance saline preparations, some Cl^- must be replaced with HCO_3^-, or else with strong anions that undergo metabolic 'disappearance' such as lactate, gluconate, or acetate. Sufficient chloride must be replaced to ensure that the fall in extracellular SID balances the A_{tot} dilution effect. In animal and human studies, this value is 24 mEq/L.[41,42]

Box 92.2 Adverse effects of metabolic acidosis

- Reduced myocardial contractility, tachy- and brady-dysrhythmias, systemic arteriolar dilatation, venoconstriction, centralisation of blood volume
- Pulmonary vasoconstriction, hyperventilation, respiratory muscle failure
- Reduced splanchnic and renal blood flow
- Increased metabolic rate, catabolism, reduced ATP synthesis, reduced 2,3-DPG synthesis
- Confusion, drowsiness
- Increased iNOS expression, pro-inflammatory cytokine release
- Hyperglycemia, hyperkalaemia
- Cell membrane pump dysfunction
- Bone loss, muscle wasting

Renal tubular acidosis (RTA)[16]

In RTA, urinary SID is high relative to the SID_{IPE}, with an inadequate nadir following an acid load. The disturbance is in renal tubular Cl^- handling, from either reduced ammonia production (Types 1 and 4), or increased chloride resorption (Type 2). Causes are legion (**Table 92.4**).

Apart from treating underlying causes and preventing hypercalcuria, management in Types 1 and 2 RTA is based on administering sodium bicarbonate or citrate to correct extracellular SID, and preventing and treating hypokalaemia using potassium citrate (not chloride). In

Table 92.4 Types of renal tubular acidosis

	TYPE 1	TYPE 2	TYPE 4
MECHANISM	Impaired distal NH_4^+ secretion	Increased proximal chloride resorption	Hyperkalaemic suppression of proximal tubular NH_4^+ production
SOME CAUSES	Idiopathic, hypercalcuric, amphotericin B, lithium carbonate, rheumatoid arthritis, Sjögren's disease, SLE, cirrhosis, renal transplant rejection, obstructive uropathy, primary hyperparathyroidism, hyperglobulinaemia	*With other proximal tubular defects (Fanconi syndrome)*: genetic, light chain nephropathy, acetazolamide, heavy metals, aminoglycosides, valproate, chemotherapy, renal transplantation, amyloidosis, paroxysmal nocturnal haemoglobinuria	*Reduced aldosterone secretion or sensitivity*: hyporeninaemia, adrenal insufficiency, ACE inhibitors, NSAIDS, cyclosporine, heparin, amiloride, spironolactone, triamterene, pentamidine, diabetes, obstructive uropathy, interstitial nephropathies, renal transplant rejection, analgesic nephropathy
SBE	Can be <−15 mEq/L	−6 to −15 mEq/L	−6 to −8 mEq/L
PLASMA $[K^+]$	Usually low	Low	High
URINE pH POST FUROSEMIDE	>5.5	<5.5 (bicarbonaturia with $NaHCO_3^-$ infusion)	Usually <5.5
URINARY AG	Positive	Negative	Usually positive
URINARY NH_4^+	Reduced	Normal or high	Usually reduced

Type 4 RTA, inciting agents are ceased, and adrenal insufficiency treated with mineralocorticoid replacement. Alkali supplements and furosemide are occasionally necessary.

Lactic acidosis

See Chapter 19.

Management of metabolic acidosis

Management is directed at the underlying cause. Care must be taken when instituting mechanical ventilation, since a sudden reduction in minute volume can be lethal. For example, an arterial pH of 6.9 and Pa_{CO_2} of 10 mmHg (1.33 kPa) implies maximal hyperventilation. If the Pa_{CO_2} suddenly returns to 'normal' (40 mmHg (5.32 kPa)), the arterial pH will fall to 6.7. If the Pa_{CO_2} rises further to 60 mmHg (7.98 kPa), the pH will be 6.6.

Administration of alkalinising agents – sodium bicarbonate, 'Carbicarb®', sodium lactate and tham[43] The term 'alkalinising agent' is preferred to 'buffer'. True chemical buffering implies resistance to pH change on addition of an acid or base, whereas an alkalinising agent increases the pH at any given P_{CO_2}.

In lactic acidosis and organic acidoses in general, it is difficult to justify the administration of alkalinising agents (see Ch. 19). However, it can be appropriate to infuse $NaHCO_3$ to correct a severe normal AGc acidosis. Other conditions where $NaHCO_3$ administration is often indicated include severe hyperkalaemia, methanol and ethylene glycol poisoning, and tricyclic and salicylate overdose. A $NaHCO_3$ dose of 1 mmol/kg increases SBE approximately 3 mEq/L.

Administering $NaHCO_3$ increases SID. The active agent is therefore sodium, not bicarbonate. NaOH is not used because of its alkalinity (pH 14). However, two problems arise from the high CO_2 content (CO_{2tot}) of $NaHCO_3$ (approximately 1028 mmol/L in a 1M solution). One is the need for expensive CO_2-impermeable containers during autoclaving and storage. The other is the possibility of paradoxical intracellular respiratory acidosis on administration. Although demonstrable in vitro,[44] this is unlikely to be a problem in clinical practice provided $NaHCO_3$ administration is slow (over 30–60 minutes) to prevent a surge in $\dot{V}CO_2$ and intravascular P_{CO_2}. This precaution should be effective except when pulmonary perfusion is massively reduced, such as in cardiac arrest.

Nevertheless the CO_{2tot} of bicarbonate preparations can be reduced, the trade-off being a rise in pH. For example in Carbicarb® (CO_{2tot}=750 mmol/L, P_{CO_2}= 2 mmHg (0.266 kPa), pH=9.8), half the monovalent bicarbonate becomes divalent carbonate. In Europe, sodium lactate (0.167M, pH 6.9) is an alternative. Note that lactate does not 'generate' bicarbonate. It is replaced by bicarbonate on metabolism to glucose by gluconeogenesis or CO_2 via the Krebs pathway.

Infusing a weak base (B_{TOT}) will also shift the Pa_{CO_2}/pH curve upward. THAM is tromethamine or tris buffer, a weak base with a pKa of 7.7 at 37°C. On addition of $THAMH^+$, buffer base charge becomes more negative to maintain electrical neutrality. SBE increases without changing SID_{IPE} or A_{tot}. THAM is CO_2-consuming, with good cell penetration, and causes an immediate intracellular metabolic and respiratory alkalosis. Presumably this phenomenon in CSF explains its propensity to cause sudden apnoea. THAM accumulates in renal impairment, and can cause hypoglycaemia, hyperosmolality, and coagulation and potassium disturbances.

Potential adverse effects of all alkalinising agents include a sudden increase in haemoglobin–oxygen affinity, the production of a hyperosmolar state, reduced $[Ca^{2+}]$ and $[Mg^{2+}]$, and rebound alkalosis on resolution of an organic acidosis.

METABOLIC ALKALOSIS

In metabolic alkalosis, SID_{IPE} is high relative to A_{tot}. Metabolic alkalosis has been described as the most common acid–base disturbance in hospital patients, but with modern definitions is more often part of a 'mixed' disorder.

Causes (Box 92.3)

Metabolic alkalosis can be precipitated by:

1. Low urinary SID (e.g. diuretics)
2. Loss of low SID enteric fluid (e.g. small gut fistulae)
3. Gain of high SID fluid (e.g. $NaHCO_3$ administration).

Clinical features

A high plasma pH (>7.55) has a number of adverse effects (**Box 92.4**). Mortality in critical illness escalates as the pH rises above 7.55, although how much is causation versus association is unclear.

Treatment

The first step is to remove the cause. Measures can then be instituted to accelerate the reduction in extracellular SID. They include:

1. Correcting effective volume depletion (reduced skin turgor, postural hypotension, high urea:creatinine ratio, urinary $[Cl^-]$<20 mmol/L). The term 'saline-responsive metabolic alkalosis' implies that saline overcomes the alkalinising renal response to hypovolaemia (low urinary SID). In fact, all metabolic alkaloses will respond if sufficient saline can be administered safely, since saline induces a 'counter' metabolic acidosis. Common colloid preparations have similar in vitro acid–base effects and could be infused as alternatives.[45]
2. Administering KCl to correct potassium depletion. The vital component is the chloride. Simplistically, potassium (strong cation) enters the depleted intracellular compartment in excess of administered chloride (strong anion), increasing SID_{IPE}. This explanation ignores associated Gibbs Donnan phenomena.
3. Acetazolamide therapy to increase urinary SID (requires adequate renal function).

Box 92.3 Metabolic alkalosis – causes

Low urinary SID	Enteric losses of low SID fluid	Gain of high SID fluid
Loop or thiazide diuretics	Pyloric stenosis, vomiting/gastric outlet obstruction, nasogastric suction	$NaHCO_3$ administration
Post-hypercapnia	Villous adenoma	Sodium citrate (plasma exchange, >8 units stored blood)
Corticosteroids	Laxative abuse	Renal replacement fluids with high SID (>35 mEq/L)
Cushing's syndrome		Milk alkali syndrome
Primary mineralocorticoid excess		
Carbenoxolone, glycyrrhetinic acid (licorice)		
Hypercalcaemia		
Milk alkali syndrome		
Magnesium deficiency		
Bartter's and Gitelman's syndromes		

Box 92.4 Severe metabolic alkalosis – multi-system effects

Central nervous system
- Vasospasm
- Seizures
- Confusion, drowsiness

Neuromuscular
- Weakness, tetany, muscle cramps

Cardiovascular
- Arrhythmias – supraventricular and ventricular
- Decreased contractility

Respiratory
- Decreased alveolar ventilation
- Atelectasis, hypoxaemia

Metabolic
- Hyperlactaemia
- Low [Pi], [Ca^{2+}], [Mg^{2+}] and [K^+]

Hemoglobin-oxygen affinity
- Initially increased (until counteracted by increased 2,3-DPG)

Box 92.5 Conditions predisposing to respiratory alkalosis

Acute	Chronic
Hypoxaemia	Pregnancy
Hepatic failure	High altitude
Sepsis	Chronic lung disease
Asthma	Neurotrauma
Pulmonary embolism	Chronic liver dysfunction
Pneumonia, acute lung injury	
CNS disorders – stroke, infection, trauma	
Drugs – salicylates, SSRI	
Opiate and benzodiazepine withdrawal	
Mechanical hyperventilation – intentional or inadvertent	
Pain, anxiety, psychosis	

4. Administration of HCl, which has a negative SID, through a central venous catheter. Minute ventilation, hypercarbia and oxygenation will usually improve. HCl can also be given indirectly, as NH_4Cl, or as arginine or lysine hydrochloride. All require hepatic deamination.
5. Renal replacement therapy.

As with metabolic acidosis, care is required when instituting mechanical ventilation. Minute volume settings should be reduced to avoid precipitating extreme alkalaemia.

RESPIRATORY ACIDOSIS

Causes (Table 92.5)

The risk is increased when CO_2 production is high and when ventilation is inefficient (large alveolar or apparatus dead space, respiratory muscle disadvantage due to hyperinflation).

Clinical features

These include the effects of acidaemia (see Box 92.2). However, acute hypercarbia has important central nervous effects, including asterixis, confusion, drowsiness, fitting and raised intracranial pressure. Hypercarbia also activates the sympatho-adrenal and renin–angiotensin systems, reducing renal perfusion, glomerular filtration rate and urine output.

Treatment

Management is directed at the underlying cause. Mechanical ventilation, either non-invasive or invasive, may be required.

RESPIRATORY ALKALOSIS

Causes

Respiratory alkalosis arises in a number of clinical scenarios (**Box 92.5**).

Clinical features

With the exception of the complications of hypoventilation, all the multisystem effects of alkalaemia apply.

Treatment

Management should be directed towards the underlying cause.

Table 92.5 Some causes of respiratory acidosis

MECHANISM/AFFECTED SITE	ACUTE	CHRONIC
Respiratory centre suppression	Sedative and narcotic drugs, CNS injury, CNS infection, brainstem vasculitis or infarction	Obesity, hypoventilation syndrome
Airway obstruction	Inhalational injury, Ludwig's angina, laryngeal trauma	Obstructive sleep apnoea, vocal cord paresis, subglottic and tracheal stenosis
Mechanical ventilation	Permissive hypercarbia	
Neural/neuromuscular	Spinal cord injury, Guillain–Barré syndrome, myasthenia gravis, muscle relaxants, envenomation, acute poliomyelitis, critical illness myoneuropathy	Phrenic nerve damage, paraneoplastic syndromes, post-polio syndrome
Muscle	Myopathy, low [K^+], high [Mg^{2+}], low [Pi], diaphragmatic injury, shock	Muscular dystrophies, motor neuron disease
Decreased chest wall compliance	Abdominal distension, burns, pneumothorax, large pleural effusions	Obesity, kyphoscoliosis, ankylosing spondylitis
Loss of chest wall integrity/geometry	Flail segment	Thoracoplasty
Increased small airways resistance	Asthma, bronchiolitis	Chronic obstructive pulmonary disease
Deceased lung compliance	Acute lung injury, pneumonia, pulmonary oedema, vasculitis, and haemorrhage	Pulmonary fibrosis

Fluid and electrolyte therapy

Anthony Delaney and Simon Finfer

The management of patients' fluid and electrolyte status requires an understanding of body fluid compartments as well as an understanding of water and electrolyte metabolism. These principles will be considered along with the commonly encountered fluid and electrolyte disturbances. Recent evidence for the use of fluid therapy in a number of common clinical scenarios will also be presented.

FLUID COMPARTMENTS (TABLE 93.1, FIG. 93.1)

TOTAL BODY WATER

In humans, water contributes approximately 60% of body weight, with organs varying in water content (**Table 93.2**). The variation of the percentage of total body weight as water, between individuals, is largely governed by the amount of adipose tissue. The average water content as a percentage of total body weight is 60% for males and 50% for females. Total body water as a percentage of total body weight decreases with age, due to a progressive loss of muscle mass, causing bone and connective tissue to assume a greater percentage of total body weight[1–3] (**Table 93.3**).

Total body water is commonly divided into two volumes: the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume.[2] Sodium balance regulates the ECF volume, whereas water balance regulates the ICF volume. Sodium excretion is normally regulated by various hormonal and physical ECF volume sensors, whereas water balance is normally regulated by hypothalamic osmolar sensors.[4]

EXTRACELLULAR FLUID

ECF is defined as all body water external to the cell, and is commonly subdivided into plasma and interstitial fluid volumes. The ECF is normally 40% of total body water and 25% of total body weight. With acute or chronic illness, ICF volume is reduced, and ECF volume is increased and may even exceed the ICF volume. The ECF volume can be divided into the plasma volume, the extracellular fluid volume, and the interstitial volume.

INTRACELLULAR FLUID

ICF is defined as all the body water within cells and, unlike the ECF compartment, is an inhomogeneous, multicompartmental entity, with different pH and ionic compositions depending upon the organ or tissue being considered. The ICF volume is often determined by inference from the difference in measurements of the total body water and ECF spaces. This estimation suffers from the inaccuracies inherent in both ECF and total body water measurements. In general, the ICF is considered to be 60% of total body water and 35% of total body weight.

TRANSCELLULAR FLUID

Fluids in this compartment have a common characteristic of being formed by transport activity of cells. The fluid is extracellular in nature and will be considered as part of the interstitial volume. It may vary from 1 to 10 L, with larger volumes occurring in diseased states (e.g. bowel obstruction or cirrhosis with ascites), and is formed at the expense of the remaining interstitial and plasma volumes.

WATER METABOLISM

Water balance is maintained by altering the intake and excretion of water. Intake is controlled by thirst, whereas excretion is controlled by the renal action of antidiuretic hormone (ADH). In health, plasma osmolalities of about 280 mOsm/kg suppress plasma ADH to concentrations low enough to permit maximum urinary dilution.[5] Above this value, an increase in ECF tonicity of about 1–2% or a decrease in total body water of 1–2 litres causes the posterior pituitary to release ADH, which acts upon the distal nephron to increase water reabsorption. Maximum plasma ADH concentrations are reached at an osmolality of 295 mOsm/kg.[5] The osmotic stimulation also changes thirst sensation and, in the conscious ambulant individual, initiates water repletion (drinking), which is more important in preventing dehydration than ADH secretion and action. Thus, in health, the upper limit of the body osmolality (and therefore serum sodium) is determined by the

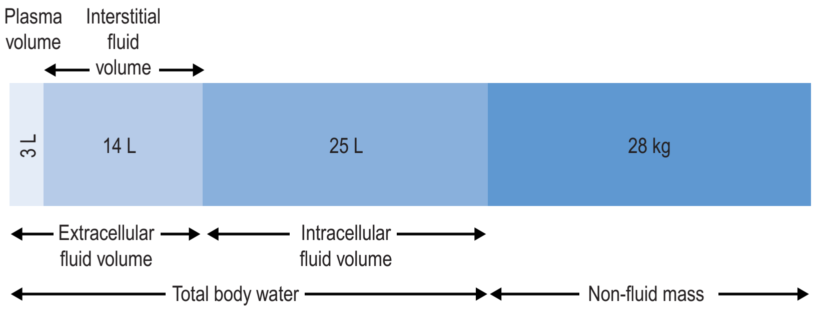

Figure 93.1 Body fluid compartments.

Table 93.1 Body fluid compartments

FLUID COMPARTMENT	VOLUME (ML/KG)	% TOTAL BODY WEIGHT
Plasma volume	45	4.5
Blood volume	75	7.5
Interstitial volume	200	20
Extracellular fluid volume	250	25
Intracellular fluid volume	350	35
Total body fluid volume	600	60

Table 93.2 Water content of various tissues

TISSUE	% WATER CONTENT
Brain	84
Kidney	83
Skeletal muscle	76
Skin	72
Liver	68
Bone	22
Adipose tissue	10

Table 93.3 Water content as a percentage of total body weight

AGE (YEARS)	MALES (%)	FEMALES (%)
10–15	60	57
15–40	60	50
40–60	55	47
>60	50	45

osmotic threshold for thirst, whereas the lower limit is determined by the osmotic threshold for ADH release.[6]

Increase in osmolality caused by permeant solutes (e.g. urea) does not stimulate ADH release. ADH may also be released in response to hypovolaemia and hypotension, via stimulation of low- and high-pressure

Table 93.4 Drugs affecting ADH secretion

STIMULATE	INHIBIT
Nicotine	Ethanol
Narcotics	Narcotic antagonists

Carbamazepine	
Amitriptyline	

baroreceptors. ADH release is extremely marked when more than 30% of the intravascular volume is lost. ADH may also be stimulated by pain and nausea, which are thought to act through the baroreceptor pathways.[4] ADH release may also be stimulated by a variety of pharmacological agents (**Table 93.4**). Renal response to ADH depends upon an intact distal nephron and collecting duct, and a hypertonic medullary interstitium. The capacity to conserve or excrete water also depends upon the osmolar load presented to the distal nephron.[4]

WATER REQUIREMENTS

Water is needed to eliminate the daily solute load, and to replace daily insensible fluid loss (**Table 93.5**). With a normal daily excretion of 600 mOsm solute, maximal and minimal secretions of ADH will cause urine osmolality to vary from 1200 to 30 mOsm/kg respectively, and the urine output to vary from 500 mL to 20 L/day respectively. Skin and lung water losses vary, and may range from 500 mL to 8 L/day depending on physical activity, ambient temperature and humidity.

DISORDERS OF OSMOLALITY

TONICITY

Osmolality is a measure of the number of osmoles per kilogram (Osm/kg) of water. The osmolality of the ECF

Table 93.5 Daily fluid balance (for a 70-kg man at rest in a temperate climate)

	INPUT (ML)			OUTPUT (ML)	
	SEEN	UNSEEN		SEEN	UNSEEN
Drink	1000	–	Urine	1000	–
Food	–	650	Skin	–	500
Water of oxidation	–	350	Lungs	–	400
			Faeces	–	100
Total	1000	1000	Total	1000	1000

is due largely to sodium salts. Clinical effects of hyperosmolality, due to excess solute, depend upon whether the solute distributes evenly throughout the total body water (e.g. permeant solutes of alcohol or urea) or distributes in the ECF only (e.g. impermeant solutes of mannitol or glucose). With impermeant solutes, hyperosmolality is associated with a shift of fluid from the ICF to the ECF compartment. Hyperosmolality due to increased impermeant solutes is known as hypertonicity. This condition may also be associated with a reduction in the serum sodium concentration (see below).

WATER EXCESS

In a 70-kg man, for every 1 litre of excess water, ECF increases by 400 mL and ICF increases by 600 mL, on average. The osmolality also decreases by 6–7 mOsm/kg and the serum sodium falls by 3.0–3.5 mmol/L.

WATER DEFICIENCY

In a 70-kg man, for every 1 litre of water loss, 600 mL is lost from the ICF and 400 mL from the ECF. The osmolality also increases by 7–8 mOsm/kg and the serum sodium rises by 3.5–4.0 mmol/L.

ELECTROLYTES

Chemical compounds in solution may either:

- Remain intact (i.e. undissociated), in which case they are called non-electrolytes (e.g. glucose, urea)
- Dissociate to form ions, in which case they are called electrolytes. Ions carry an electrical charge (e.g. Na^+, Cl^-). Ions with a positive charge are attracted to a negative electrode or cathode, and hence are called 'cations'. Conversely, ions with a negative charge travel towards a positive electrode or anode and are called 'anions'. Each body water compartment contains electrolytes with different composition and concentration (**Table 93.6**).

Table 93.6 Electrolyte composition of body fluid compartments

	ICF (MMOL/L)	ECF (MMOL/L) PLASMA	ECF (MMOL/L) INTERSTITIAL
Sodium	10	140	145
Potassium	155	3.7	3.8
Chloride	3	102	115
Bicarbonate	10	28	30
Calcium (ionised)	<0.01	1.2	1.2
Magnesium	10	0.8	0.8
Phosphate	105	1.1	1

SODIUM

Sodium is the principal cation of the ECF and accounts for 86% of the ECF osmolality. In a 70-kg man, total body sodium content is 4000 mmol (58 mmol/kg) and is divided into a number of compartments (**Table 93.7**).

Table 93.7 The sodium compartments in a 70-kg man

	TOTAL (MMOL)	(MMOL/KG)
Total body sodium	4000	58
Non-exchangeable bone sodium	1200	17
Exchangeable sodium	2800	40
Intracellular sodium	250	3
Extracellular sodium	2400	35
Exchangeable bone sodium	150	2

ECF concentration of sodium varies between 134 and 146 mmol/L. The intracellular sodium concentration varies between different tissues, and ranges from 3 to 20 mmol/L.

The standard Western society dietary sodium intake is about 150 mmol/day, but the daily intake of sodium varies widely, with urinary losses ranging from <1 to >240 mmol/day.[7] Sodium balance is influenced by renal hormonal and ECF physical characteristics. The complete renal adjustment to an altered sodium load usually requires 3–4 days before balance is restored.

Box 93.1 Common causes of hyponatraemia

1. Spurious result
   - Isotonic
     - Hyperlipidaemia
     - Hyperproteinaemia
   - Hypertonic
     - Hyperglycaemia
     - Mannitol, glycerol, glycine or sorbitol excess
2. Water retention
   - Renal failure
   - Hepatic failure
   - Cardiac failure
   - Syndrome of inappropriate ADH secretion
   - Drugs
   - Psychogenic polydipsia
3. Water retention and salt depletion
   - Postoperative, post trauma or patients with excess fluid losses given inappropriate fluid replacement
   - Adrenocortical failure
   - Diuretic excess

HYPONATRAEMIA

Hyponatraemia is defined as serum sodium less than 135 mmol/L and may be classified as isotonic, hypertonic or hypotonic, depending upon the measured serum osmolality (**Box 93.1**).

Isotonic hyponatraemia

Plasma normally contains 93% water and 7% solids (5.5% proteins, 1% salts and 0.5% lipids). If the solid phase is elevated significantly (e.g. in hyperlipidaemia or hyperproteinaemia), any device that dilutes a specific amount of plasma for analysis will give falsely lower values for all measured compounds. This effect produces 'factitious hyponatraemia' and is associated with a normal measured serum osmolality.[8] Measurement of plasma sodium by an ion-selective electrode is not affected by the volume of plasma 'solids' and therefore 'pseudohyponatraemia' will not occur with this method.[8]

Hypertonic hyponatraemia

In patients who have hypertonicity due to increased amounts of impermeant solutes (e.g. glucose, mannitol, glycerol or sorbitol), a shift of water from the ICF to the ECF occurs to provide osmotic equilibration, thus diluting the ECF sodium. Such resultant hyponatraemia is often associated with an increased measured osmolality. For example, in the presence of hyperglycaemia, for every 3 mmol/L rise in glucose the serum sodium decreases by 1 mmol/L.[9]

Hypotonic hyponatraemia

Hyponatraemia is almost always caused by an excess of total body water, due to excessive hypotonic or water-generating i.v. fluids (e.g. 1.5% glycine, 0.45% saline or 5% glucose) or to excessive ingestion of water, particularly in the presence of high circulating ADH concentrations. It may rarely be caused by loss of exchangeable sodium or potassium. In the latter circumstances, a loss of approximately 40 mmol of sodium or potassium, without a change in total body water content, is required to lower the serum sodium by 1 mmol/L. As hyponatraemia may be associated with an alteration in both total body water and total body sodium, the ECF may be increased (hypervolaemia), decreased (hypovolaemia) or exhibit no change (isovolaemia).[5]

In health, a fluid intake up to 15–20 litres may be tolerated before water is retained and hyponatraemia occurs. In psychogenic polydipsia, if the water intake exceeds the renal capacity to form dilute urine, water retention and hyponatraemia will occur. With this disorder, the plasma osmolality exceeds urine osmolality. In circumstances where ADH is increased (e.g. hypovolaemia, hypotension, pain or nausea), or where renal response to ADH is altered (i.e. in renal, hepatic, pituitary, adrenal or thyroid failure), water retention occurs with lower intakes of fluid.

SPECIFIC CAUSES OF HYPONATRAEMIA

Transurethral resection of prostate (TURP) syndrome

Clinical features The TURP syndrome consists of hyponatraemia, cardiovascular disturbances (hypertension, hypotension, bradycardia), an altered state of consciousness (agitation, confusion, nausea, vomiting, myoclonic and generalised seizures) and, when using glycine solutions, transient visual disturbances of blurred vision, blindness and fixed dilated pupils, following TURP. It has also been described following endometrial ablation.[10] It may occur within 15 minutes or be delayed for up to 24 hours postoperatively,[11] and is usually caused by an excess absorption of the irrigating fluid, which contains 1.5% glycine with an osmolality of 200 mOsm/kg. Hyponatraemic syndromes have also been described when irrigating solutions containing 3% mannitol or 3% sorbitol have been used. Symptomatology usually occurs when >1 litre of 1.5% glycine or >2–3 litres of 3% mannitol or sorbitol are absorbed.[12]

The excess absorption of irrigating fluid causes an increase in total body water (which is often associated with only a small decrease in plasma osmolality), hyponatraemia (as glycine, sorbitol or mannitol reduces the sodium component of ECF osmolality) and an increase in the osmolar gap.[12,13] When glycine is used, other features include hyperglycinaemia (up to 20 mmol/L; normal plasma glycine concentrations range from 0.15 to 0.3 mmol/L), hyperserinaemia (as serine is a major metabolite of glycine), hyperammonaemia (following deamination of glycine and serine), metabolic acidosis and hypocalcaemia (due to the glycine metabolites glyoxylic acid and oxalate). Because glycine is an inhibitory neurotransmitter, and as it passes freely into the intracellular compartment when glycine solutions are used, hyperglycinaemia may be

more important in the pathophysiology of this disorder than a reduction in body fluid osmolality and cerebral oedema.[14]

Treatment Treatment is largely supportive with the management of any reduction in plasma osmolality being based on the measured plasma osmolality and not the plasma sodium. If the measured osmolality is >260 mOsm/kg and mild neurological abnormalities exist, and if the patient is haemodynamically stable with normal renal function, close observation and reassurance (e.g. the visual disturbances are reversible and will last for less than 24 hours) are usually all that is needed. If the patient is hypotensive and bradycardic with severe and unresolving neurological abnormalities, haemodialysis may be warranted. Hypertonic saline is used only if the measured osmolality is <260 mOsm/kg and severe non-visual neurological abnormalities exist.[15]

Syndrome of inappropriate ADH secretion (SIADH)

This syndrome is a form of hyponatraemia in which there is an increased concentration of ADH inappropriate to any osmotic or volume stimuli that normally affect ADH secretion.[16] Diagnostic criteria and common causes are listed in **Boxes 93.2** and **93.3** respectively.

Clinical features Whereas cerebral manifestations are usually absent when the sodium concentration exceeds 125 mmol/L, progressive symptomatology of headache, nausea, confusion, disorientation, coma and seizures are often observed when plasma sodium is below 120 mmol/L.[17]

Treatment Initial treatment should be fluid restriction with close monitoring of serum sodium. If serum sodium concentration is not increasing with fluid restriction, judicious administration of sodium as intravenous normal or hypertonic saline may be required. As the true duration and rapidity of onset of hyponatraemia are often unclear, the presence and severity of symptoms may be used as the trigger for active correction of hyponatraemia.[17] The evidence base available to guide therapy is limited and there is consequently no consensus on the optimum rate at which to correct the serum sodium concentration. The major concern is to avoid neurological damage from untreated seizures, cerebral oedema, or myelinolysis.[17] In the absence of good evidence, recommended rates at which to increase the sodium concentration vary from 0.5 to 2 mmol/L per hour. Unless the treating clinician feels that more rapid correction is indicated, it seems prudent to correct the serum sodium concentration at a slower rather than a faster rate.

Cerebral salt wasting

Cerebral salt wasting (CSW) is a syndrome occurring in patients with a cerebral lesion and an excess renal loss of sodium and chloride.[18] The exact aetiology of the syndrome remains unclear. Although hyponatraemia is not necessary for the diagnosis, the syndrome is commonly associated with hyponatraemia.[19] The diagnosis of CSW is suspected in patients with a cerebral lesion, such as subarachnoid haemorrhage, traumatic brain injury or a cerebral tumour, when there is an elevated urine output, with elevated urinary sodium in the absence of a physiological cause for increased sodium excretion.[19] The syndrome can be differentiated from the SIADH, as patients with CSW will have evidence of ECF depletion (e.g. negative fluid balance, tachycardia, increased haematocrit, increased urea, low central venous pressure) as opposed to the SIADH where ECF volume will be normal or slightly expanded.[20] Treatment of patients involves exclusion of other causes of hyponatraemia and increased urine output, replacement of sodium and fluid losses, and possibly fludrocortisone.[21]

SPECIFIC TREATMENTS USED FOR HYPONATRAEMIA

Hypertonic saline

Hypertonic saline, most commonly as 3% saline, is used as a therapy for patients with symptomatic

Box 93.2 Criteria for the diagnosis of syndrome of inappropriate antidiuretic hormone (SIADH)

- Hypotonic hyponatraemia
- Urine osmolality greater than plasma osmolality
- Urine sodium excretion greater than 20 mmol/L
- Normal renal, hepatic, cardiac, pituitary, adrenal and thyroid function
- Absence of hypotension, hypovolaemia, oedema and drugs affecting ADH secretion
- Correction by water restriction

Box 93.3 Aetiologies of syndrome of inappropriate antidiuretic hormone (SIADH)

Ectopic ADH production by tumours
- Small cell bronchogenic carcinoma
- Adenocarcinoma of the pancreas or duodenum
- Leukaemia
- Lymphoma
- Thymoma

Central nervous system disorders
- Cerebral trauma
- Brain tumour (primary or secondary)
- Meningitis or encephalitis
- Brain abscess
- Subarachnoid haemorrhage
- Acute intermittent porphyria
- Guillain–Barré syndrome
- Systemic lupus erythematosus

Pulmonary diseases
- Viral, fungal and bacterial pneumonias
- Tuberculosis
- Lung abscess

hyponatraemia. Due to the osmolarity (1000 mOsm/L) of 3% saline, it must be given through a central line, and care must be taken to avoid the known complications of its use, including chronic heart failure and central pontine and extrapontine myelinolysis (osmotic demyelination syndrome).[22,23] Careful haemodynamic and electrolyte monitoring throughout saline administration is required. There is still no uniform agreement that osmotic demyelination is produced by a rapid correction of hyponatraemia.

Although hypertonic saline has been proposed as a therapy for raised intracranial pressure in a number of clinical settings,[24] its use remains controversial.[25] In a recent methodologically sound (adequate allocation concealment, blinded and using intention-to-treat analysis) randomised clinical trial, which included 229 patients with severe traumatic brain injury, resuscitation with 250 mL of 7.5% saline was not associated with improved mortality or functional outcomes compared with Hartmann's solution.[26]

Vasopressin receptor antagonists

V_2 receptor antagonists, such as lixivaptan, tolvaptan and OPC-31260, have recently been developed. These agents come from a novel class of non-peptide agents that bind to V_2 receptors in the distal tubule of the kidney and prevent vasopressin-mediated aquaporin mobilisation, and thus promote aquaresis.[27] These agents have been trialled as therapeutic options for the treatment of hyponatraemia in a number of clinical settings including hyponatraemia associated with heart failure, cirrhosis and SIADH.[27,28] At present the role of V_2 receptor antagonists in the management of hyponatraemia in the critically ill remains uncertain.

HYPERNATRAEMIA

Hypernatraemia, defined as a serum sodium greater than 145 mmol/L, is always associated with hyperosmolality and may be caused by excessive administration of sodium salts (bicarbonate or chloride), water depletion or excess sodium and loss of water (**Box 93.4**).

Excessive ingestion of sodium salts is rare, but intravenous infusion of large volumes of sodium-containing fluids is common in the management of hospitalised patients. Hypernatraemia often occurs in the recovery phase of acute illness when spontaneous diuresis or diuretic therapy results in more rapid clearance of free water than sodium. Pure water depletion is uncommon, unless water restriction is applied to a patient who is unconscious or unable to obtain or ingest water, as the thirst response normally corrects water depletion. If it occurs, the serum sodium concentration increases, in association with loss of both ECF and ICF.

Clinical features

Hypernatraemia usually produces symptoms if the serum sodium exceeds 155–160 mmol/L (i.e. osmolality >330 mOsm/kg). The clinical features include increased temperature, restlessness, irritability, drowsiness, lethargy, confusion and coma.[29] Convulsions are uncommon. The diminished ECF volume may reduce cardiac output, thereby reducing renal perfusion, leading to prerenal renal failure.

Box 93.4 Causes of hypernatraemia

Water depletion
- Extrarenal loss
  - Exposure
  - GIT losses (often with excess saline replacement)
- Renal loss
  - Osmotic diuresis – urea, mannitol, glycosuria
  - Diabetes insipidus
    - Neurogenic
      - Post-traumatic, fat embolism
      - Metastatic tumours, craniopharyngioma, pinealoma, cysts
      - Meningitis, encephalitis
      - Granulomas (TB, sarcoid)
      - Guillain–Barré syndrome
      - Idiopathic
    - Nephrogenic
      - Congenital
      - Hypercalcaemia, hypokalaemia
      - Lithium
      - Pyelonephritis
      - Medullary sponge kidney
      - Polycystic kidney
      - Post-obstructive uropathy
      - Multiple myeloma, amyloid, sarcoid

Salt gain
- Hypertonic, saline or sodium bicarbonate

Treatment

For pure water depletion, this consists of water administration. If i.v. fluid is required, 5% glucose or hypotonic saline solution (0.45% saline) is often used, as sterile water infusion causes haemolysis. In rare cases, i.v. sterile water may be used by administering through a central venous catheter.[30] Since rapid rehydration may give rise to cerebral oedema, the change in serum sodium should be no greater than 0.5 mmol/L per hour.[29]

POTASSIUM

Potassium is the principal intracellular cation and accordingly (along with its anion) fulfils the role of the ICF osmotic provider. It also plays a major role in the functioning of excitable tissues (e.g. muscle and nerve). As the cell membrane is 20-fold more permeable to potassium than to sodium ions, potassium is largely responsible for the resting membrane potential. Potassium also influences carbohydrate metabolism and glycogen and protein synthesis.

Total body potassium is 45–50 mmol/kg in the male (3500 mmol/70 kg) and 35–40 mmol/kg (2500 mmol/65 kg) in the female; 95% of the total body potassium is exchangeable. As ECF potassium ranges from 3.1 to 4.2 mmol/L, the total ECF potassium ranges from 55 to 70 mmol. About 90% of the total body potassium is intracellular: 8% resides in bone, 2% in ECF water and 70% in skeletal muscle. With increasing age (and decreasing muscle mass), total body potassium decreases.

FACTORS AFFECTING POTASSIUM METABOLISM

The potassium content of cells is regulated by a cell wall pump-leak mechanism. Cellular uptake is by the Na^+/K^+ pump, which is driven by Na^+/K^+ ATPase. Movement of potassium out of the cell is governed by passive forces (i.e. cell membrane permeability and chemical and electrical gradients to the potassium ion).

Acidosis promotes a shift of potassium from the ICF to the ECF, whereas alkalosis promotes the reverse shift. Hyperkalaemia stimulates insulin release, which promotes a shift of potassium from the ECF to the ICF, an effect independent of the movement of glucose. Beta$_2$-adrenergic agonists promote cellular uptake of potassium by a cyclic AMP-dependent activation of the Na^+/K^+ pump, whereas alpha-adrenergic agonists cause a shift of potassium from the ICF to the ECF.[31] Aldosterone increases the renal excretion of potassium; glucocorticoids are also kaliuretic, an effect that may be independent of the mineralocorticoid receptor.

Normally, mechanisms to reduce the ECF potassium concentration (by increasing renal excretion and shifting potassium from the ECF to the ICF) are very effective. However, mechanisms to retain potassium in the presence of potassium depletion are less efficient, particularly when compared with those of sodium conservation. Even with severe potassium depletion, urinary loss of potassium continues at a rate of 10–20 mmol/day. Metabolic alkalosis also enhances renal potassium loss, by encouraging distal nephron Na^+/K^+, rather than Na^+/K^+ exchange.

HYPOKALAEMIA

Hypokalaemia is defined as a serum potassium of less than 3.5 mmol/L (or plasma potassium less than 3.0 mmol/L). It may be due to decreased oral intake, increased renal or gastrointestinal loss, or movement of potassium from the ECF to the ICF (**Box 93.5**).

Clinical features

These include weakness, hypotonicity, depression, constipation, ileus, ventilatory failure, ventricular tachycardias (characteristically torsades de pointes), atrial tachycardias and even coma.[32] With prolonged and severe potassium deficiency, rhabdomyolysis and thirst and polyuria, due to the development of renal diabetes insipidus, may occur. The ECG changes are relatively non-specific, and include prolongation of the PR interval, T-wave inversion and prominent U-waves.

Box 93.5 Causes of hypokalaemia

- Inadequate dietary intake (urine K^+ <20 mmol/L)
- Abnormal body losses
  - Gastrointestinal (urine K^+ <20 mmol/L)
    - Vomiting, nasogastric aspiration
    - Diarrhoea, fistula loss
    - Villous adenoma of the colon
    - Laxative abuse
  - Renal (urine K^+ >20 mmol/L)
    - Conn's syndrome
    - Cushing's syndrome
    - Bartter's syndrome
    - Ectopic ACTH syndrome
      - Small-cell carcinoma of the lung
      - Pancreatic carcinoma
      - Carcinoma of the thymus
  - Drugs
    - Diuretics
    - Corticosteroids
    - Carbapenems, amphotericin B, gentamicin
    - Cisplatin
  - Renal tubular acidosis
  - Magnesium deficiency
- Compartmental shift
  - Alkalosis
  - Insulin
  - Na^+/K^+ ATPase stimulation
    - Sympathomimetic agents with β_2 effect
    - Methylxanthines
  - Barium poisoning
  - Hypothermia
  - Toluene intoxication
  - Hypokalaemic periodic paralysis
  - Delayed following blood transfusion (see Ch. 95)

Treatment

Intravenous or oral potassium chloride will correct hypokalaemia, particularly if it is associated with metabolic alkalosis. If the patient has renal tubular acidosis and hypokalaemia, potassium acetate or citrate may be preferred to potassium chloride. Intravenous administration of potassium should normally not exceed 40 mmol/h, and plasma potassium should be monitored at 1–4-hourly intervals.[33] In patients with acute myocardial infarction and hypokalaemia, traditional recommendations were to maintain the serum potassium at 4.0 mmol/L,[34] but more recently the need to administer supplemental potassium when the serum potassium is >3.5mmol/L has been questioned.[35]

HYPERKALAEMIA

Hyperkalaemia is defined as a serum potassium greater than 5.0 mmol/L or plasma potassium greater than 4.5 mmol/L. It may be artefactual (from sampling errors

Box 93.6 Causes of hyperkalaemia

Collection abnormalities
- Delay in separating RBC
- Specimen haemolysis
- Thrombocythaemia

Excessive intake
- Transiently following blood transfusion (see Ch. 95)
- Exogenous (i.e. i.v. or oral KCl, massive blood transfusion)
- Endogenous (i.e. tissue damage)
  - Burns, trauma
  - Rhabdomyolysis
  - Tumour lysis

Decrease in renal excretion
- Drugs
  - Spironolactone, triamterene, amiloride
  - Indometacin
  - Captopril, enalapril
- Renal failure
- Addison's disease
- Hyporeninaemic hypoaldosteronism

Compartmental shift
- Acidosis
- Insulin deficiency
- Digoxin overdosage
- Succinylcholine
- Arginine hydrochloride
- Hyperkalaemic periodic paralysis
- Fluoride poisoning

such as in vitro haemolysis); true hyperkalaemia may be due to excessive intake, severe tissue damage, decreased excretion or body fluid compartment shift (**Box 93.6**).

Clinical features

These include tingling, paraesthesia, weakness, flaccid paralysis, hypotension and bradycardia. The characteristic ECG effects include peaking of the T-waves, flattening of the P-wave, prolongation of the PR interval (until sinus arrest with nodal rhythm occurs), widening of the QRS complex, and the development of a deep S-wave. Finally, a sine wave ECG pattern that deteriorates to asystole may occur at serum potassium levels of 7 mmol/L or greater.

Treatment

This is directed at the underlying cause, and may include dialysis. Rapid management of life-threatening hyperkalaemia may be achieved by:[36]

- Calcium chloride 5–10 mL i.v. of 10% (3.4–6.8 mmol, which is used to reduce the cardiac effects of hyperkalaemia)
- Sodium bicarbonate, 50–100 mmol i.v.
- Glucose, 50 g i.v. with 10 units of soluble insulin
- Oral and rectal resonium A, 50 g
- Diuresis with furosemide, 40–80 mg i.v.
- Beta agonists e.g. salbutamol 5–10 mg nebulised.

CALCIUM

Almost all (99%) of the body calcium (30 mmol or 1000 g or 1.5% body weight) is present in bone. A small but significant quantity of ionised calcium exists in the ECF, and is important for many cellular activities including secretion, neuromuscular impulse formation, contractile functions and clotting. Normal daily intake of calcium is 15–20 mmol, although only 40% is absorbed. The average daily urinary loss is 2.5–7.5 mmol. The total ECF calcium of 40 mmol (2.20–2.55 mmol/L) exists in three forms: 40% (1.0 mmol/L) is bound to protein (largely albumin), 47% is ionised (1.15 mmol/L) and 13% is complexed (0.3 mmol/L) with citrate, sulphate and phosphate. The ionised form is the physiologically important form, and may be acutely reduced in alkalosis, which causes a greater amount of the serum calcium to be bound to protein.[37] Although the serum ionised calcium can be measured, the total serum calcium is usually measured, and this can vary with the serum albumin concentrations. A correction factor can be used to offset the effect of serum albumin on serum calcium: this is 0.02 mmol/L for every 1 g/L increase in serum albumin (up to a value of 40 g/L), added to the measured calcium concentration. For example, if measured serum calcium is 1.82 mmol/L, and serum albumin is 25 g/L, corrected serum calcium $= 1.82 + [(40-25) \times 0.02]$ mmol/L $= 2.12$ mmol/L. It has been suggested that ionised calcium, where available, is a better indicator of calcium status in the critically ill.[38]

HYPOCALCAEMIA

Common causes of hypocalcaemia include hypoparathyroidism and pseudohypoparathyroidism, septic shock, acute pancreatitis and rhabdomyolysis.[39] Clinical features of reduced serum ionised calcium include tetany, cramps, mental changes and decrease in cardiac output. Symptomatic hypocalcaemia should be treated with i.v. calcium, as either calcium chloride or calcium gluconate. It should be remembered that 1 mL of calcium chloride has three times as much elemental calcium as 1 mL of calcium gluconate, and so the former is the preferred formulation in acute situations. Calcium should be administered via a central vein when practical, owing to the risk of tissue damage if extravasated.[39]

HYPERCALCAEMIA

The clinical features of hypercalcaemia include nausea, vomiting, pancreatitis, polyuria, polydipsia, muscular weakness, mental disturbance and ectopic calcification. Some of the common causes of hypercalcaemia include endocrine diseases such as hyperparathyroidism and thyrotoxicosis, renal failure, malignancy, thiazide diuretics and prolonged immobilisation.[39]

Severe hypercalcaemia (>3.3 mmol/L) or more moderate symptomatic hypercalcaemia will require specific therapy. A cause for the elevated calcium concentration

should be sought, and specific treatment may be warranted. General measures include restoration of intravascular volume with normal saline, followed by the use of a loop diuretic such as furosemide to promote calcium excretion. The use of bisphosphonates, such as pamidronate, is recommended for severe cases.[40] Other therapies to consider include steroids, calcitonin and mithramycin.

MAGNESIUM

Magnesium is primarily an intracellular ion that acts as a metallo-coenzyme in numerous phosphate transfer reactions. It has a critical role in the transfer, storage and utilisation of energy.

In humans, the total body magnesium content is 1000 mmol, and the plasma concentrations range from 0.70 to 0.95 mmol/L. The daily oral intake is 8–20 mmol (40% of which is absorbed) and the urinary loss, which is the major source of excretion of magnesium, varies from 2.5 to 8 mmol/day.[41]

HYPOMAGNESAEMIA

Hypomagnesaemia is caused by decreased intake or increased loss (**Box 93.7**). Clinical features include neurological signs of confusion, irritability, delirium tremors, convulsions and tachyarrhythmias. Hypomagnesaemia is often associated with resistant hypokalaemia and hypocalcaemia. Treatment consists of i.v. magnesium sulphate as a bolus of 10 mmol, administered over 5 minutes, followed by 20–60 mmol/day.

Box 93.7 Causes of magnesium deficiency

- Gastrointestinal disorders
  - Malabsorption syndromes
  - GIT fistulas
  - Short-bowel syndrome
  - Prolonged nasogastric suction
  - Diarrhoea
  - Pancreatitis
  - Parenteral nutrition
- Alcoholism
- Endocrine disorders
  - Hyperparathyroidism
  - Hyperthyroidism
  - Conn's syndrome
  - Diabetes mellitus
  - Hyperaldosteronism
- Renal diseases
  - Renal tubular acidosis
  - Diuretic phase of acute tubular necrosis
- Drugs
  - Aminoglycosides
  - Carbenicillin, ticarcillin
  - Amphotericin B
  - Diuretics
  - Cis-platinum
  - Ciclosporin

HYPERMAGNESAEMIA

Hypermagnesaemia is often caused by excessive administration of magnesium salts or conventional doses of magnesium in the presence of renal failure. Clinical features include drowsiness, hyporeflexia and coma, vasodilatation and hypotension, and conduction defects of sinoatrial and atrioventricular nodal block and asystole may occur. Treatment is directed towards increasing excretion of the ion, which may require dialysis. Intravenous calcium chloride may be used for rapidly treating the cardiac conduction defects.[41]

MAGNESIUM THERAPY

There are increasing reports of the use of magnesium as a therapy for a variety of conditions. A randomised control trial of over 10 000 women with pre-eclampsia demonstrated the efficacy of magnesium in the prevention of eclampsia,[42] and it is also a recommended treatment for established eclampsia. It has been used to treat atrial fibrillation, to achieve both rate control and reversion to sinus rhythm in a number of settings, including post cardiac surgery, and in the emergency department.[43,44] Magnesium, given either intravenously or nebulised, may be beneficial for patients with acute severe asthma.[45,46] There are also preliminary trials to suggest that magnesium may prevent delayed cerebral ischaemia due to vasospasm in patients with subarachnoid haemorrhage.[47]

PHOSPHATE

While most of the body phosphate exists in bone, 15% is found in the soft tissues as ATP, red blood cell 2,3-DPG, and other cellular structural proteins, including phospholipids, nucleic acids and phosphoproteins. Phosphate also acts as a cellular and urinary buffer.[41]

HYPOPHOSPHATAEMIA

Hypophosphataemia may be caused by a decreased intake, increased excretion or intracellular redistribution (**Box 93.8**). Although hypophosphataemia may be symptom-free, clinical features have been described that include paraesthesia, muscle weakness, seizures,

Box 93.8 Causes of hypophosphataemia

- Hyperparathyroidism
- Vitamin D deficiency
- Vitamin-D-resistant rickets
- Renal tubular acidosis
- Alkalosis
- Parenteral nutrition
- Alcoholism
- Refeeding syndrome

coma, rhabdomyolysis and cardiac failure. Hypophosphataemia may be a prominent feature of the refeeding syndrome when it may be accompanied by other electrolyte disturbances such as hypokalaemia and hypomagnesaemia. Treatment consists of close monitoring and replacement as oral or i.v. sodium or potassium phosphate, 50–100 mmol/24 h.

HYPERPHOSPHATAEMIA

Hyperphosphataemia is usually caused by an increased intake or decreased excretion (**Box 93.9**). Clinical features include ectopic calcification of nephrocalcinosis, nephrolithiasis and band keratopathy. Treatment may require haemodialysis; otherwise oral aluminium hydroxide and even hypertonic glucose solutions to shift ECF phosphate into the ICF can be used.

Box 93.9 Causes of hyperphosphataemia

- Rhabdomyolysis
- Renal failure (acute or chronic)
- Vitamin D toxicity
- Acidosis
- Tumour lysis
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Diphosphonate (bisphosphonate) therapy
- Excess i.v. administration

FLUID AND ELECTROLYTE REPLACEMENT THERAPY

GENERAL PRINCIPLES

In critical illness many of the body's normal homeostatic mechanisms are deranged and basic life-preserving senses such as hunger and thirst may be abolished by disease processes or by treatments such as the use of sedation. As a result, the survival of critically ill patients depends on the administration of appropriate volumes of fluids, and appropriate quantities of electrolytes and nutrition by their medical and nursing attendants. Basal requirements for water, electrolytes and nutrients are discussed in Chapter 94. In addition to basal requirements, many critically ill patients have abnormal fluid and electrolyte losses that must be replaced; examples are discussed below.

GASTROINTESTINAL LOSSES

The daily volumes and composition of gastrointestinal tract (GIT) secretions in mmol/L are shown in **Table 93.8**. Clinical effects of fluid loss from the GIT are largely determined by the volume and composition of the fluid, and therapy is usually directed at replacing the losses. Gastric fluid loss (e.g. from vomiting and nasogastric suction) results in water, sodium, hydrogen ion, potassium and chloride depletion. Hence metabolic alkalosis, hypokalaemia, hypotension and dehydration develop if the saline and potassium chloride losses are not correctly replaced.

Pancreatic and biliary fluid losses (e.g. pancreatic or biliary fistula)

These may result in hyperchloraemic acidosis with hypokalaemia, hypotension and dehydration if the losses of bicarbonate, potassium and saline are not correctly replaced.

Intestinal losses (e.g. fistula or ileostomy losses, diarrhoea and ileus)

These result in hypokalaemia, hypotension and dehydration if the saline and potassium losses are not replaced.

RESUSCITATION FLUIDS

Systemic hypotension is a common feature of acute critical illness and first-line treatment is usually the administration of intravenous resuscitation fluid. The fluids available to clinicians to maintain or expand intravascular volume include crystalloids, colloids and blood products; the properties of colloid solutions and blood products are discussed in Chapters 95 and 96.

Whether the choice of resuscitation fluid influences patients' outcomes has been the subject of long-running debate. This debate, which was been fuelled by the conflicting and inconclusive results of a number of meta-analyses[48–49] may now be nearing resolution. Recent data from clinical trials may help guide clinicians with the choice of resuscitation fluids. The first adequately powered trial, the Saline versus Albumin Fluid

Table 93.8 Daily volume and electrolyte composition of GIT secretions

ELECTROLYTES (MMOL/L)	VOL. (L)	H^+	Na^+	K^-	CL^-	HCO_3^-
Saliva	0.5–1.0	0	30	20	10–35	0–15
Stomach	1.0–2.5	0–120	60	10	100–120	0
Bile	0.5	0	140	5–10	100	40–70
Pancreatic	0.75	0	140	5–10	70	40–70
Small and large gut	2.0–4.0	0	110	5–10	100	25

Evaluation (SAFE) Study, found that saline and albumin produced comparable outcomes in a heterogeneous population of adult patients,[50] but in patients with traumatic brain injury resuscitation with albumin was associated with a significant increase in mortality[51] Choice of fluid for resuscitation may also be important in patients with severe sepsis. In a trial led by the Scandinavian Critical Care Trials Group[52] patients with severe sepsis who were resuscitated with hydroxylethyl starch 130/0.42 in Ringer's acetate had an increased risk of death compared with resuscitated only with Ringer's acetate. Although rapid fluid resuscitation remains a strongly recommended treatment for adults with severe sepsis in the developed world, a trial in African children with severe infections has challenged the assumption that this is the correct strategy in all situations. In the FEAST study, children with severe infections who received 20–40 mL/kg of either normal saline or 5% albumin as fluid boluses had an increased risk of death compared with those who received only maintenance fluids.[53] The relevance of these findings for adult and developed world medicine is unclear. Further investigator-initiated trials are currently under way (such as the CHEST study, NCT00935168) and their results may further assist clinicians to develop evidence-based fluid resuscitation strategies.

Enteral and parenteral nutrition

Richard Leonard

It is standard practice to provide nutritional support to critically ill patients in order to treat existing malnutrition and minimise wasting of lean body mass. However, despite the universality of this practice, the evidence underlying it is often conflicting and of disappointingly poor quality.[1] The failings in the evidence seem to extend to some of the resulting debates, in which extreme positions are defended.[2,3] Inevitably these difficulties have led many to seek clarity in meta-analyses; perhaps equally inevitably,[4,5] these have usually disappointed. On so basic a question as the relative merits of enteral and parenteral routes of feeding, the two most recent meta-analyses have produced conflicting results.[6,7]

The problem persists with the publication of numerous clinical practice guidelines,[8–14] which differ radically in important areas.[15] Three studies have examined the effect of introducing such guidelines into ICUs using a cluster-randomisation design; whereas the first – the ACCEPT study – found a 10% reduction in mortality, which narrowly failed to reach statistical significance,[8] the other two detected no outcome benefit.[16,17]

NUTRITIONAL ASSESSMENT

Objective assessment of nutritional status is difficult in ICU, because disease processes confound methods used in the general population. Anthropometric measures such as triceps skin-fold thickness and mid-arm circumference may be obscured by oedema. Voluntary handgrip strength is impractical in unconscious patients. Laboratory measures, including transferrin, pre-albumin and albumin levels, lymphocyte counts, and skin-prick test reactivity, are abnormal in critical illness. Clinical evaluation – the so-called subjective global assessment – is better than objective measurement at predicting morbidity.[18] Historical features of malnutrition include weight loss, poor diet, gastrointestinal symptoms, reduced functional capacity and a diagnosis associated with poor intake. Physical signs include loss of subcutaneous fat, muscle wasting, peripheral oedema and ascites.

Although laboratory measures are of little value in assessing nutritional status in critically ill patients, they may be useful before elective major surgery. Serum albumin and operative site are closely associated with the risk of postoperative complications.[19] This raises the possibility that outcomes may be improved by treating preoperative malnutrition identified by a simple screening test.

PATIENT SELECTION AND TIMING OF SUPPORT

There are reasonable grounds to believe that it is better to provide nutritional support to critically ill patients than not to do so. This belief is based on the close association between malnutrition, negative nitrogen and calorie balance and poor outcome, and the inevitability of death if starvation continues for long enough. In otherwise healthy humans this takes several weeks to occur. There is also some direct evidence from one study of jejunal feeding in patients operated on for severe pancreatitis,[20] in which the control group received only intravenous fluids until normal diet resumed. Mortality markedly decreased in the group receiving nutritional support.

Two questions arise from this, relating to the important problem of when nutritional support should start:

- How long is it safe to leave a critically ill patient without nutrition? In other words, which patients need to be fed artificially because they would otherwise be starved for too long, and who can safely wait until they are able to eat?
- If the patient will clearly exceed whatever period is deemed reasonable, is it better to begin feeding immediately? In other words, when should we start to feed?

Quite good evidence now supports the early institution of nutritional support, and the trend is both to tolerate much shorter periods without nutrition and to begin feeding more rapidly after initial resuscitation.

In 1997, recommendations from a conference sponsored by the US National Institutes of Health, the American Society for Parenteral and Enteral Nutrition and the American Society for Clinical Nutrition suggested that nutritional support be started in any critically ill patient unlikely to regain oral intake within 7–10 days.[21] The basis for this was that, at a typical

nitrogen loss of 20–40 g/day, dangerous depletion of lean tissue may occur after 14 days of starvation. Others have suggested a maximum acceptable delay of 3–7 days. Small studies comparing earlier with delayed institution of nutritional support have had conflicting results. A meta-analysis comparing early (first 48 hours after admission to ICU) with late enteral feeding revealed a reduction in infectious complications.[22] Two subsequent meta-analyses comparing early and delayed enteral feeding both found a reduction in mortality with early support,[23,24] although the authors commented that the total number of patients and the methodological quality of the studies included were both low. Early institution of enteral feeding within 24 hours of ICU admission in patients unlikely to feed orally in that time was an important component of the ACCEPT study guideline (**Fig. 94.1**).[8] The weight of evidence is presently in favour of this more aggressive approach, but it can hardly be regarded as conclusively proven.[25]

NUTRITIONAL REQUIREMENTS OF THE CRITICALLY ILL

ENERGY

Some muscle wasting and nitrogen loss are unavoidable in critical illness, despite adequate energy and protein provision.[26] This fact, coupled with the realisation that caloric requirements had previously been overestimated, has led to downward revision of intake, a process which may be continuing. In 1997, the American College of Chest Physicians (ACCP) published guidelines recommending a daily energy intake of 25 kcal/kg,[11] and this has remained the standard target energy intake for critically ill patients.

More recently, concerns have been raised that this standard intake may be excessive. An observational study found lower mortality in those patients who received 9–18 kcal/kg/day than in those with higher

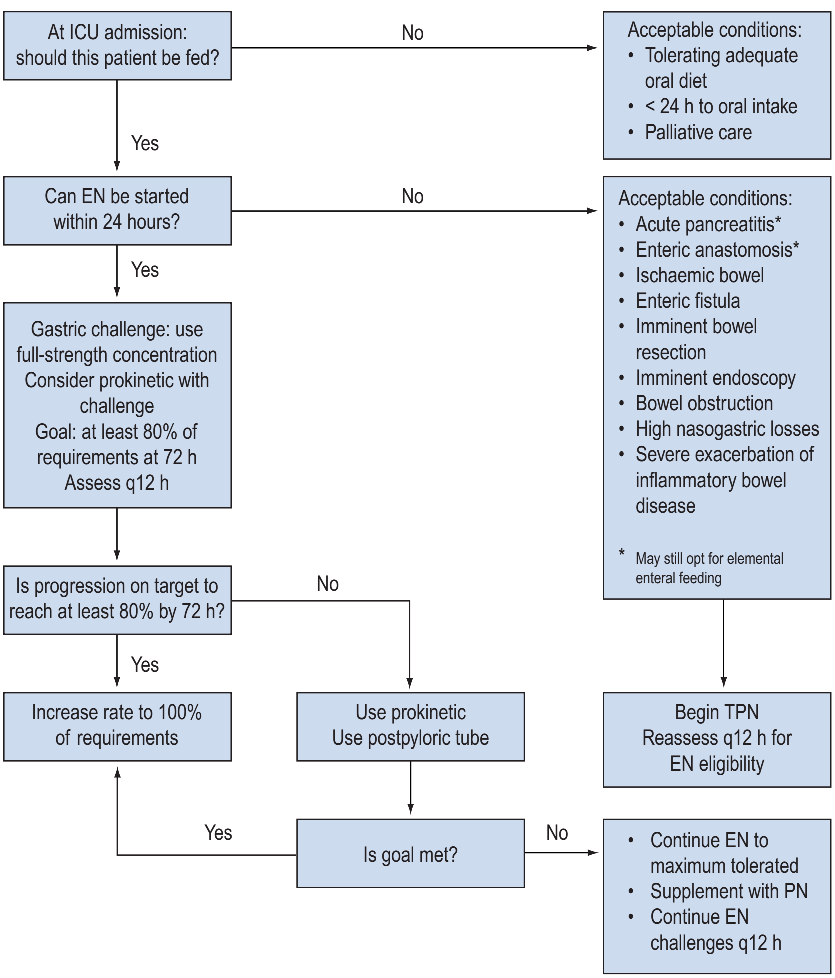

Figure 94.1 Algorithm for nutritional support used in the ACCEPT trial.[8] EN=enteral nutrition; PN=parenteral nutrition.

and lower intakes.[27] One small study showed no change in ICU or 28-day mortality, but a reduction in hospital and 180-day mortality, in patients fed with a target of 60–70% of their calculated requirement compared with those fed at 90–100% of required energy intake. However, the difference in delivered intakes was small.[28] In contrast, a much larger study comparing full enteral feeding with 'trophic' low-dose feeding for the first week after patients were admitted with acute lung injury could not identify any effect.[29] At present, unequivocal benefits of hypocaloric feeding have yet to be demonstrated in large prospective trials. It remains extremely important to realise that enterally fed patients frequently fail to achieve their target intake, and that significant under-feeding is certainly associated with worse outcomes.[27,30,31]

Attempts have also been made to tailor the energy provided to critically ill patients to their individual needs. Two methods are commonly used: indirect calorimetry and predictive equations. Indirect calorimetry is the gold standard, and its use is becoming easier with the availability of devices designed for ICU patients. It permits measurement of the resting energy expenditure (REE). This value excludes the energy cost of physical activity, which increases later in the course of an ICU admission.[32] Calorimetry reveals deviations from values predicted by equations, such that two-thirds of patients in one study were being either under- or overfed.[33] On the other hand, it could not be shown that outcomes are improved by the use of calorimetry,[34] although a more recent study showed a trend towards reduced hospital mortality in the group whose feeding was calorimetrically guided (and who received in consequence a higher caloric intake).[35] Moreover, there are no clear data to relate measured REE to total energy expenditure in the individual patient. Presently most ICUs do not use calorimetry.

There are several equations claiming to predict basal metabolic rate (BMR) on the basis of weight, sex and age. Correction factors exist to convert predictions of BMR into estimated energy expenditure by adjusting for such variables as diagnosis, pyrexia and activity. In the past these correction factors have been excessive and may have contributed to overfeeding; a more conservative approach is now advocated. The recommendations of the British Association for Parenteral and Enteral Nutrition are:[36]

1. Determine BMR from Schofield's equations (**Table 94.1**).
2. Adjust BMR for stress (**Table 94.2**).
3. Add a combined factor for activity- and diet-induced thermogenesis:
   bed-bound, immobile: +10%
   bed-bound, mobile/sitting: +20%
   mobile around ward: +25%.

Despite the popularity of measurements or estimates of energy expenditure it is not clear that their routine use improves outcome. Many clinicians dispense with both and simply aim to deliver the ACCP's recommended target of 25 kcal/kg/day.

Table 94.1 Basal metabolic rate in kcal/day by age and gender[37]

AGE	FEMALE	MALE
15–18	13.3 W+690	17.6 W+656
18–30	14.8 W+485	15.0 W+690
30–60	8.1 W+842	11.4 W+870
>60	9.0 W+656	11.7 W+585

W=weight in kg.

Table 94.2 Stress adjustment in the calculation of basal metabolic rate[36]

Partial starvation (>10% weight loss)	Subtract 0–15%
Mild infection, inflammatory bowel disease, postoperative	Add 0–13%
Moderate infection, multiple long bone fractures	Add 10–30%
Severe sepsis, multiple trauma (ventilated)	Add 25–50%
Burns 10–90%	Add 10–70%

PROTEIN

Assessment of nitrogen balance by measuring urinary urea nitrogen is too variable to be useful in estimating protein requirements in ICU.[38] As there is an upper limit to the amount of dietary protein that can be used for synthesis,[39] there is no benefit from replacing nitrogen lost in excess of this. A daily nitrogen provision of 0.15–0.2 g/kg/day is therefore recommended for the ICU population; this is equivalent to 1–1.25 g protein/kg/day. Severely hypercatabolic individuals, such as those with major burns, are given up to 0.3 g nitrogen/kg/day, or nearly 2 g protein/kg/day.[36]

MICRONUTRIENTS

Critical illness increases the requirements for vitamins A, E, K, thiamine (B1), B3, B6, vitamin C and pantothenic and folic acids.[40] Thiamine, folic acid and vitamin K are particularly vulnerable to deficiency during total parenteral nutrition (TPN). Renal replacement therapy can cause loss of water-soluble vitamins and trace elements. Deficiencies of selenium, zinc, manganese and copper have been described in critical illness, in addition to the more familiar iron-deficient state. Subclinical deficiencies in critically ill patients are thought to cause immune deficiency and reduced

Table 94.3 Vitamin requirements in critical illness[40]

VITAMIN	FUNCTION	DOSE
Vitamin A	Cell growth, night vision	10 000–25 000 IU
Vitamin D	Calcium metabolism	400–1000 IU
Vitamin E	Membrane antioxidant	400–1000 IU
Beta carotene*	Antioxidant	50 mg
Vitamin K	Activation of clotting factors	1.5 μg/kg/day
Thiamine (vitamin B1)	Oxidative decarboxylation	10 mg
Riboflavin (vitamin B2)	Oxidative phosphorylation	10 mg
Niacin (vitamin B3)	Part of NAD, redox reactions	200 mg
Pantothenic acid	Part of coenzyme A	100 mg
Biotin	Carboxylase activity	5 mg
Pyridoxine (vitamin B6)	Decarboxylase activity	20 mg
Folic acid	Haematopoiesis	2 mg
Vitamin B12	Haematopoiesis	20 μg
Vitamin C	Antioxidant, collagen synthesis	2000 mg

*Not strictly a vitamin.

Table 94.4 Trace element requirements in critical illness[40]

ELEMENT	FUNCTION	DOSE
Selenium	Antioxidant, fat metabolism	100 μg
Zinc	Energy metabolism, protein synthesis, epithelial growth	50 mg
Copper	Collagen cross-linking, ceruloplasmin	2–3 mg
Manganese	Neural function, fatty acid synthesis	25–50 mg
Chromium	Insulin activity	200 mg
Cobalt	B12 synthesis	
Iodine	Thyroid hormones	
Iron	Haematopoiesis, oxidative phosphorylation	10 mg
Molybdenum	Purine and pyridine metabolism	0.2–0.5 mg

Table 94.5 Water and electrolyte requirements per kilogram per day

Water	30 ml
Sodium	1–2 mmol
Potassium	0.7–1 mmol
Magnesium	0.1 mmol
Calcium	0.1 mmol
Phosphorus	0.4 mmol

resistance to oxidative stress. Suggested requirements for micronutrients in critically ill patients vary between authors and depending on route of administration; the most comprehensive guidance[40] is reproduced in **Tables 94.3** and **94.4**. More recent but broadly similar recommendations for some compounds are also available.[41,42]

Commercial preparations of both enteral and parenteral feeding solutions contain standard amounts of micronutrients. Supplementation of intake of certain antioxidant vitamins and trace elements above these levels is discussed below.

WATER AND ELECTROLYTES

Water and electrolyte requirements vary widely depending on the patient's condition; typical basal intakes are shown in **Table 94.5**.

ROUTE OF NUTRITION

When possible patients should be fed enterally. The advantages over the parenteral route are the lower cost, greater simplicity and possibly fewer infective complications. These appear to be the only advantages of the enteral route. Despite the fervour with which some pursue the debate,[2,3] there is little basis for the widespread belief that the enteral route provides a clear benefit in terms of outcome.

Two hypotheses are commonly advanced in support of the putative superiority of enteral feeding. First, it appears that the lipid contained within TPN is immunosuppressive. Intravenous lipid is known to suppress neutrophil and reticulo-endothelial system function, and a comparison of TPN with and without lipid in critically ill trauma patients showed a lower complication rate in those not receiving lipid.[43] Secondly, enteral feeding may protect against infective complications. Absence of complex nutrients from the intestinal lumen is followed in rats by villus atrophy and reduced cell mass of the gut-associated lymphoid tissue (GALT). Starved humans show these changes to a much lesser extent. Lymphocytes produced in the GALT are redistributed to the respiratory tract, and contribute heavily to mucosal immunity. In mice, this contribution is lost

during TPN. The possibility that multiple organ failure may be driven by translocation of bacteria or endotoxin across an impaired mucosal barrier has been extensively investigated in animals. Although it is known that TPN is associated with increased gut permeability to macromolecules in humans, this does not seem to result in translocation.[44] Although translocation does occur following surgery, and seems to be associated with sepsis,[45] a causal relation with multiple organ failure is unproven.

In fact, a reduction in septic morbidity has been found only in certain groups, primarily abdominal trauma victims,[46,47] in whom parenteral nutrition was associated with a higher incidence of abdominal abscess and pneumonia. A third study found no difference.[48] In head-injured patients there is one trial showing no effect and one each supporting either route; however, in the study favouring TPN the enteral nutrition group were significantly underfed.[49–51] None of these studies is less than 20 years old, and the techniques of both enteral and parenteral feeding have changed a great deal in that time. Reductions in infective complications have also been found using enteral feeding in pancreatitis.[52] In contrast, no benefit was found in sepsis, though enteral feeding was instituted late.[53]

More recent systematic analyses have, as mentioned earlier, produced conflicting results. One found a reduction in infectious complications with enteral feeding, but no difference in mortality.[7] The most recent meta-analysis considered only high-quality trials using an intention-to-treat principle. It showed a clear reduction in mortality in patients fed parenterally.[6]

This mortality difference disappeared when early enteral and parenteral feeding were compared. On this basis, as in the ACCEPT study, the authors recommended early use of the enteral route, with recourse to parenteral nutrition if this was not possible. A well-powered randomised study comparing early parenteral with early enteral feeding is presently recruiting.[54] However, in view of the practical and financial advantages of enteral feeding, it will probably need to find a significant mortality difference in favour of the parenteral route if it is to change the present pragmatic preference for enteral feeding.

One related area of controversy remains the practice – advocated in the European guidelines, deprecated in the two North American ones – of supplementing partially successful but inadequate enteral intake with intravenous feeding relatively early in the course of an ICU admission.[9,13,14] One large multicentre study compared early parenteral supplementation of inadequate enteral intake (within 48 hours of ICU admission) with supplementation delayed until day 8.[55] There was no mortality difference, but patients in the delayed-supplementation group left ICU earlier and suffered fewer infective complications. However, interpretation of this study is complicated by the fact that the early-supplementation group received 25–30 kcal/kg/day, raising the possibility that high intake, rather than the route of feeding, was responsible for the increase in infections. The study also used tight glycaemic control. These differences from common practice make it difficult to generalise the findings. It is presently uncertain whether, when and at what dose parenteral feeding should be used to supplement inadequate enteral intake, but very early, aggressive intravenous supplementation does not seem warranted.

ENTERAL NUTRITION

ACCESS

Nasal tubes are preferred to oral, except in patients with a basal skull fracture, in whom there is a risk of cranial penetration. A large-bore (12–14 Fr) nasogastric tube is usually used at first. Once feeding is established and gastric residual volumes (see below) no longer need to be checked this can be replaced with a more comfortable fine-bore tube. A stylet is needed to assist in passage of fine-bore tubes. The position of all tubes must be checked on X-ray before feeding is started, as misplacement is not uncommon and intrapulmonary delivery of feed is potentially fatal.

Nasojejunal tubes may be beneficial if impaired gastric emptying is refractory to prokinetic agents[8] (see below); their unselective use is not indicated even in patients with mildly elevated gastric residual volumes.[56,57] Spontaneous passage through the pylorus following blind placement is not reliable, but may be increased by the administration of single doses of 200 mg erythromycin or 20 mg metoclopramide.[58] Endoscopic or fluoroscopic assistance is needed for truly reliable transpyloric tube placement, although use of electromagnetic guidance systems may obviate the logistic difficulties these traditional methods entail.[59] There are conflicting data on the question of whether nasojejunal feeding reduces the risk of aspiration or ventilator-associated pneumonia.[57,60,61] The lack of evidence of a clear benefit, coupled with the cost and logistic difficulty of placing them, precludes the routine use of nasojejunal tubes for all patients.

An alternative method of access in those needing long-term enteral feeding is percutaneous gastrostomy, which can be performed endoscopically or radiologically. Percutaneous jejunal access can be obtained either via a gastrostomy or by direct placement during incidental laparotomy.

REGIMEN

Slowly building up the rate of feeding is not proven to avoid diarrhoea or high gastric residual volumes. Head-injured patients fed with target intake from the outset have fewer infective complications,[62] and the practice has subsequently been shown to be safe in unselected ICU patients.[63] Nevertheless, it is presently

common practice to start delivering around 30 mL/h and build up to the target intake depending on tolerance, as judged by gastric residual volumes. These are assessed by aspiration of the tube every 4 hours. Gastric residual volumes over 150 mL on two successive occasions have been associated with an increased incidence of ventilator-associated pneumonia in one study;[64] in contrast others have found no link between high residual volumes and the risk of aspiration.[65] Nevertheless, if the residual volume is consistently greater than 200 mL, treatment with prokinetic agents (metoclopramide 10 mg q. 8 h or erythromycin 250 mg q. 12 h intravenously) appears to increase tolerance of feeding, though there is no discernible effect on mortality or morbidity.[58] This is unsurprising in light of two recent studies showing that it is safe to tolerate gastric residual volumes up to 500 mL[66] or even not to check the volume at all.[67] An interesting report that acupuncture is more effective than a combination of metoclopramide, cisapride and erythromycin requires confirmation.[68] In refractory cases a nasojejunal tube often permits successful enteral feeding, because small bowel function is resumed quicker than gastric emptying. A nasogastric tube is still needed to drain the stomach. Diarrhoea, abdominal distension, nausea and vomiting may suggest intolerance, despite low gastric volumes. Absence of bowel sounds is common in ventilated patients and should not be taken to indicate ileus.

Fine-bore tubes should not be aspirated as this causes them to block. Various folk remedies have been tried for unblocking tubes, including instillation of Coca-Cola™, fruit juice and pancreatic enzyme supplements. The instillates should be left in situ for an hour or more.

COMPOSITION

Commercially available enteral feeding solutions vary widely in composition. Polymeric feeds contain intact proteins (derived from whey, meat, soy isolates and caseinates) and carbohydrates in the form of oligo- and polysaccharides. These require pancreatic enzymes for absorption.

Elemental feeds with defined nitrogen sources (amino acids or peptides) are not of benefit when used routinely, but may enable feeding when small bowel absorption is impaired, for instance in pancreatic insufficiency or following prolonged starvation. Lipids are usually provided by vegetable oils consisting mostly of long-chain triglycerides, but some also contain more easily absorbed medium-chain triglycerides. The proportion of non-protein calories provided as carbohydrate is usually two-thirds.

Electrolyte composition varies widely, with sodium- and potassium-restricted formulations available. Vitamins and trace elements are usually added by the manufacturers so that daily requirements are present in a volume containing roughly 2000 kcal. The possible benefits of providing additional doses of some of these substances to critically ill patients are considered below.

COMPLICATIONS

Enteral feeding is an independent risk factor for ventilator-associated pneumonia.[69] Sinusitis due to nasogastric intubation may necessitate changing to an orogastric tube. Fine-bore tubes are vulnerable to misplacement in the trachea or to perforation of the pharynx, oesophagus, stomach or bowel. Percutaneous endoscopic gastrostomy is associated with a high 30-day all-cause mortality in acutely ill patients, in whom it may be best avoided.[70] Other complications include insertion site infection, serious abdominal wall infection and peritonitis. Surgically placed jejunostomies can cause similar problems, and may also obstruct the bowel.

Diarrhoea is common in ICU patients, particularly those being fed enterally. It is often multifactorial and causes considerable distress and morbidity, particularly when the patient is repeatedly soiled with watery stool. Common causes include antibiotic therapy, *Clostridium difficile* infection, faecal impaction and a non-specific effect of critical illness. Malabsorption, lactose intolerance, prokinetic agents, magnesium, aminophylline, quinidine and medications containing sorbitol (for instance, paracetamol syrup and cimetidine) are occasional culprits. Rate of administration of enteral feed also plays a role. Faecal impaction, medication-induced diarrhoea and *Clostridium difficile* infection must be excluded or treated, while malabsorption may respond to elemental diet. Slowing the rate of feeding sometimes helps; diluting the formula does not. It is unclear whether addition of probiotics to enteral feed is of benefit; one small study has suggested they may reduce the incidence of diarrhoea, whereas another showed no benefit to patients with established feed-related diarrhoea.[71,72]

Metabolic complications include electrolyte abnormalities and hyperglycaemia. Severely malnourished patients are at risk of refeeding syndrome (see below) if nutritional support is begun too rapidly.

PARENTERAL NUTRITION

Parenteral nutritional support is indicated when adequate enteral intake cannot be established within an acceptable time. In some cases absolute gastrointestinal failure is obvious, whereas in others it becomes apparent only after considerable efforts to feed enterally have failed. As discussed above, there is increasing evidence that if enteral feeding cannot be established early then the parenteral route should be used until it can. Nevertheless, the aim in all patients fed intravenously should be to revert to enteral feeding as this becomes possible.

Box 94.1 Minimum monitoring during TPN – less stable patients may require more intensive surveillance

Nursing	Weekly (at least)
Temperature	Full blood picture
Pulse	Coagulation screen
Blood pressure	Liver function tests
Respiratory rate	Magnesium, calcium and phosphate
Fluid balance	Weight
Blood sugar (4-hourly when commencing feed)	**As indicated**
Daily (at least)	Zinc
Review of fluid balance	Uric acid
Review of nutrient intake	
Blood sugar	
Urea, electrolytes and creatinine	

The question of whether to supplement inadequate enteral feeding with intravenous support has also been discussed earlier.

Parenteral feeding solutions may be prepared from their component parts under sterile conditions. Ready-made solutions also exist, but any necessary additions must be made in the same way.

In ICU patients the daily requirements are infused continuously over 24 hours. Careful biochemical and clinical monitoring is important, particularly at the outset (**Box 94.1**).

ACCESS

The major concern with central venous access for TPN is prevention of infection. The following considerations apply.[73]

- *Insertion site:* subclavian lines have lower infection rates than internal jugular or femoral lines.
- *Tunnelling* may reduce infection rates in internal jugular lines but apparently not in short-term subclavian lines. It is not recommended for routine use.
- *Expertise* of operator and adequacy of ICU *nurse staffing levels* affect infection rate.
- *Skin preparation:* 2% chlorhexidine in alcohol is the most effective.
- *Sterile technique:* maximal sterile barrier procedures (mask, cap, gown, gloves, and large drape) are known to reduce catheter-related bacteraemia rates sixfold. There is a bewildering resistance to use of these precautions outside ICUs.
- *Dressings:* permeable polyurethane transparent dressings are superior to impermeable.
- *Antimicrobial catheters:* catheters coated with either chlorhexidine and silver sulfadiazine or rifampicin and minocycline are several times less likely to cause bacteraemia than standard polyurethane catheters. The duration of the anti-infective effect appears to be longer with the antibiotic-coated catheters (2 weeks versus 1).
- *Scheduled exchange* has not been proven to reduce catheter-related sepsis.
- *Guide-wire exchange* is associated with increased bacteraemia rates, which in routine use outweigh the reduced mechanical complications.

In practice pre-existing central access is used in the first instance. If a multi-lumen catheter is used, one lumen should be dedicated to administration of TPN and not used for any other purpose. Three-way taps should be avoided and infusion set changes carried out daily under sterile conditions. For long-term TPN (more than 2 months) specialised catheters with a tunnelled cuff or a subcutaneous port are recommended.

COMPOSITION

ENERGY

Energy is provided by a combination of carbohydrate and lipid. The optimal balance between the two is unknown; often 30–40% of non-protein energy is given as lipid. Alternatively, glucose may be relied upon for almost all the energy, with lipid being infused once or twice a week to provide essential fatty acids.

Glucose is the preferred carbohydrate and is infused as a concentrated solution. Exceeding the body's capacity to metabolise glucose (4 mg/kg/min in the septic patient) can lead to hyperglycaemia, lipogenesis and excess CO_2 production. Endogenous insulin secretion increases to control blood sugar levels. However, many patients require additional insulin, particularly diabetics. This may be infused separately, but when requirements are stable it is more safely added to the TPN solution. Persistent hyperglycaemia is better addressed by reducing the glucose infusion rate than by large doses of insulin.

Lipid provides essential fatty acids (linoleic and linolenic acids) and is a more concentrated energy source than glucose. It may thus avoid the complications of excess glucose administration. However, there are concerns of immunosuppression from lipid infusion, as discussed above. Current lipid preparations consist of soybean oil emulsified with glycerol and egg phosphatides. Replacement of some or all of the soybean oil with olive-oil- or fish-oil-based lipids or with medium-chain triglycerides has been proposed to offer immunological benefits; however, clear evidence of this has so far been elusive.[74]

NITROGEN

Nitrogen is supplied as crystalline solutions of L-amino acids. Commercially available preparations vary in their provision of conditionally essential amino acids. Glutamine, tyrosine and cysteine are absent from many because of instability.

MICRONUTRIENTS

Vitamin and trace element preparations are added to TPN solutions in appropriate amounts. Thiamine, folic acid and vitamin K are particularly vulnerable to depletion and additional doses may be necessary.

ELECTROLYTES

Amino acid preparations contain varying quantities of electrolytes; additional amounts may need to be added to the solution.

COMPLICATIONS

Parenteral nutrition has the potential for severe complications.

- *Catheter-related sepsis* is addressed above. Other complications of central venous cannulation are discussed elsewhere.
- *Electrolyte abnormalities* include hypophosphataemia, hypokalaemia and hypomagnesaemia, especially in the first 24–48 hours.
- *Hyperchloraemic metabolic acidosis* may result from amino acid solutions with a high chloride content. Replacing some chloride with acetate in the TPN solution will resolve this where necessary.
- *Rebound hypoglycaemia* may occur when TPN is discontinued suddenly. TPN should be weaned over a minimum of 12 hours. If it cannot be continued, an infusion of 10% dextrose should be started and blood sugars closely monitored.
- *Refeeding syndrome* may occur when normal intake is resumed after a period of starvation. It is associated with profound hypophosphataemia, and possibly hypokalaemia and hypomagnesaemia. With the restoration of glucose as a substrate, insulin levels rise and cause cellular uptake of these ions. Depletion of adenosine triphosphate (ATP) and 2,3-diphosphoglyceric acid (2,3-DPG) results in tissue hypoxia and failure of cellular energy metabolism. This may manifest as cardiac and respiratory failure, with paraesthesiae and seizures also reported. Thiamine deficiency may also play a part.
- *Liver dysfunction* is common during TPN. Causes include hepatic steatosis, intrahepatic cholestasis and biliary sludging from gallbladder inactivity. The problems necessitating TPN in the first place may also cause liver dysfunction.
- *Deficiencies* of trace elements and vitamins (especially thiamine, folic acid and vitamin K) may occur.

NUTRITION AND SPECIFIC DISEASES

ACUTE RENAL FAILURE

The advent of continuous renal replacement therapy means that dietary fluid and protein restriction is rarely necessary in ICU. Use of specialised lipid or amino acid formulations in TPN is not supported by evidence, and in general normal nutritional support is appropriate in acute renal failure.

LIVER DISEASE[21,75]

Energy requirements in ICU patients are not altered by the presence of chronic liver disease. Lipolysis is increased, so lipid must be used with caution to avoid hypertriglyceridaemia (not more than 1 g/kg/day). Protein restriction may be required in chronic hepatic encephalopathy; starting with 0.5 g/kg/day the dose may be cautiously increased towards a normal intake. Hepatic encephalopathy may in part be due to depletion of branched-chain amino acids (BCAAs) permitting increased cerebral uptake of aromatic amino acids, which produce inhibitory neurotransmitters. In protein-intolerant patients the use of feeds enriched with BCAAs may permit greater protein intake without worsening encephalopathy. Their routine use is not indicated.[76] Thiamine and fat-soluble vitamin deficiencies are common in patients with chronic liver disease. Fulminant hepatic failure reduces gluconeogenesis; hypoglycaemia is a common problem necessitating glucose infusion. Lipid is well tolerated. Energy and protein requirements are similar to those above. BCAAs have not been shown to be superior to standard amino-acid solutions.

RESPIRATORY FAILURE

Oxidation of fat produces less carbon dioxide than glucose. There have been attempts to use this to assist in weaning from mechanical ventilation by providing 50% of energy intake as lipid, with mixed results. Avoidance of overfeeding is much more important. The supplementation of omega-3 fatty acids in patients with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) is discussed below.

ACUTE PANCREATITIS

Formerly, TPN was a cornerstone of the management of severe acute pancreatitis to minimise pancreatic stimulation. This has changed with the publication of studies showing both gastric and jejunal feeding to be safe, effective and associated with reductions in infective complications compared with TPN.[51,77] Elemental feeds and pancreatic enzyme supplements are logical if malabsorption is a problem. Despite the shift towards enteral feeding of patients with pancreatitis, some can be fed only intravenously.

OBESITY

Although both the US clinical practice guideline and a subsequent consensus workshop recommend hypocaloric, high-protein feeding for obese patients, the strength of the recommendation is low and the

evidence for it weak.[14,78] Their suggested caloric requirement is 22–25 kcal/kg ideal body weight/day or 11–14 kcal/kg actual body weight/day, of which 60–70% should actually be provided, together with 2 g/kg/day protein. No other guideline makes such a recommendation. At present there is insufficient evidence to justify feeding obese patients differently from others.

ADJUNCTIVE NUTRITION

Certain substances have been used as adjuncts to feeding solutions, in attempts to modulate the metabolic and immune responses to critical illness. In general no conclusive benefit has yet been shown in unselected critically ill patients. The situation has been complicated by a tendency to study several compounds simultaneously, at arbitrary doses and in heterogeneous populations, then to perform retrospective subgroup analysis in order to demonstrate an effect. The evidence would be a great deal clearer if supplements with an established therapeutic window were evaluated individually. Such interventions are at least as much matters of pharmacology as of nutrition, and should be investigated as such.

GLUTAMINE

Glutamine serves as an oxidative fuel and nucleotide precursor for enterocytes and immune cells, mainly lymphocytes, neutrophils and macrophages. It also appears to regulate the expression of many genes related to signal transduction and to cellular metabolism and repair. During catabolic illness glutamine is released in large quantities from skeletal muscle in order to supply this need. In these circumstances it may become 'conditionally essential' and is vulnerable to depletion, with potentially adverse effects on gut barrier and immune function, which may in turn impair the ability to survive a sustained period of critical illness once glutamine stores are depleted.

The evidence on glutamine supplementation in critical illness remains somewhat contradictory. Reductions in infectious complications and length of ICU stay were shown in small early studies of enterally fed trauma and burns patients, but a much larger study in unselected ICU patients found no effect on any outcome.[79] Intravenous supplementation with glutamine in patients fed by either route (but mostly enterally) showed a reduction in ICU mortality in the treatment arm on a per protocol analysis. However, this was not accompanied by any improvement in illness severity scoring, was not detectable at 6 months, and was not present on an intention-to-treat analysis.[80] Routine glutamine supplementation in enterally fed ICU patients is at present not supported by evidence.

TPN solutions have historically contained no glutamine because of problems with stability and solubility. These have now been overcome by use of dipeptides, but clinical studies of intravenous glutamine supplementation during TPN have also been conflicting. One early trial in ICU patients requiring TPN showed a reduction in late mortality that became apparent only after 20 days, and persisted at 6 months.[81] A similar finding of reduction in late mortality was confined to those requiring TPN for more than 9 days.[82] These studies are often cited as supporting the concept of glutamine as a conditionally essential amino acid that becomes depleted during prolonged intravenous feeding. In contrast, the SIGNET study was unable to find a benefit from providing glutamine for 7 days to parenterally fed ICU patients.[83] It has been argued that this simply reflected an inadequate period either to produce or to correct glutamine depletion. In the absence of evidence of harm, some ICUs now supplement all TPN with glutamine; other more selective units reserve it for those likely to require intravenous feeding for more than 9 days.

SELENIUM

Selenium is necessary in the regulation of glutathione peroxidase, the major scavenging system for oxygen free radicals. Low plasma selenium levels are common in ICU patients, and a number of small studies have shown potential benefits, but these could not be reproduced in two recent larger trials.[83,84]

ANTIOXIDANT VITAMINS

Vitamins A, C and E are also involved in systemic defence against oxidant stress, and have been studied in various combinations and doses, with and without selenium or omega-3 fatty acids. Of the trials not using other adjuncts, only one has shown a reduction in deaths using large enteral doses of vitamins C and E; the control group, however, had a very high mortality rate.[85] It is hard to recommend routine supplementation with antioxidant vitamins on present evidence.

ARGININE AND IMMUNONUTRITION

Arginine is a non-essential amino acid that acts as a precursor of nitric oxide, polyamines (important in lymphocyte maturation) and nucleotides. Animal studies suggest enhanced cell-mediated immunity and survival when arginine is supplemented. Several commercially available enteral feeding solutions combine omega-3 fatty acids, arginine, nucleotides and in one case glutamine to produce so-called immune-enhancing diets. There is some evidence for their use following burn injury or major surgery, but little in general ICU patients. Subsequent meta-analysis suggested an increase in mortality when arginine supplementation was given to septic patients,[86] and interim safety assessment of a trial led to its early cessation when this finding was replicated in the subgroup of patients with sepsis.[87]

There has been continued interest in using feeds enhanced with omega-3 fatty acids, often in combination with antioxidant vitamins. Some studies have found benefits in patients with ALI, ARDS or sepsis, leading some guideline-emitting bodies to support this practice. However, these results could not be repeated by other more recent studies in which individual components were evaluated separately,[88,89] and current knowledge does not warrant supplementation with omega-3 fatty acids.

Blood transfusion

James P Isbister

Blood component therapy has a central therapeutic role in clinical medicine, but blood banking and transfusion medicine have tended to focus on the blood component supply rather than the demand/patient perspective. The clinical focus should naturally be on 'what is best for the patient?' and not, 'what is best for the blood supply?' This shift from blood product focus to problem-based focus is now referred to as patient blood management.[1–3]

Demand for blood components continues to increase owing to the greater burden of chronic disease due to ageing of the population, increasing severity of illness of intensive care unit (ICU) patients and both a widening range of clinical indications for blood components and newer blood-intensive surgical procedures. This is being tempered by greater focus on appropriate use.

When prescribing blood component therapy, the clinical problem and patient's needs must be accurately identified and clearly understood. Often therapy is required for haematological deficiencies until the basic disease process can be corrected (e.g. surgical control for acute haemorrhage, or support for bone marrow suppression until the marrow recovers). Therapy may be aimed at controlling the effects of a deficiency or preventing secondary problems. Alternatively, the indication is passive immunotherapy (e.g. Rhesus prophylaxis) or high-dosage intravenous immunoglobulin as immunomodulatory therapy.

In recent years the role of blood transfusion in a wide range of clinical settings is being critically reassessed, especially in relationship to the labile blood components (red cell and platelet concentrates and fresh frozen plasma). Careful risk assessment and the use of blood conservation techniques have made 'bloodless' surgery possible in most uncomplicated elective surgical settings. Added to the uncertainty about the indications and benefits of allogeneic blood transfusion is the accumulating evidence that blood transfusion is an independent risk factor for poorer clinical outcomes. Clearly many transfusions are both indicated and lifesaving, but it is appropriate that there is greater focus on techniques to minimise exposure, transfusion alternatives and closer attention to the quality and immediate efficacy of blood components.

There is a dearth of evidence supporting a role for red cell concentrates in improving clinical outcomes for haemodynamically stable patients, indeed the contrary appears to be the case.[4,5]

Traditionally, transfusion has been regarded as the 'default' decision when there is clinical uncertainty. The benefits of transfusion have been assumed with little or no evidence to support this assumption and patients are thereby unnecessarily exposed to potential morbidity or even mortality. Given that the decision-making process for using blood component therapy can be difficult, that indications may be controversial or when there is no evidence for potential benefit, there are good common sense and scientifically evidence-based reasons to adopt a non-transfusion default position.[6,7] If allogeneic blood component therapy can be avoided, the potential hazards cease to be an issue.

Both evidence-based transfusion medicine and the fact that blood is altruistically donated should ensure that blood is seen as a valuable and unique natural resource that should be conserved and managed appropriately. It should be used as therapy only when there is evidence for potential benefit, when alternatives have been considered and potential for harm has been minimised. Potential hazards must be balanced against benefits and wherever possible the benefits and risks should be explained to the patient/relatives.

In considering the use of allogeneic blood transfusion the following questions need to be addressed:

- What is the timeframe of the decision-making process?
- Is it an elective decision?
- What is the haemopoietic defect?
- What is the most appropriate therapy for the patient?
- Are there alternatives to allogeneic transfusion?
- What component is indicated and where should it be obtained?
- Except for serological compatibility are there any other patient-specific requirements (e.g. irradiated, CMV-negative)
- How should the component be administered and monitored?
- What are the potential hazards of the blood component therapy?
- Can the risk of adverse effects be avoided or minimised?
- What is the cost of the haemotherapy?

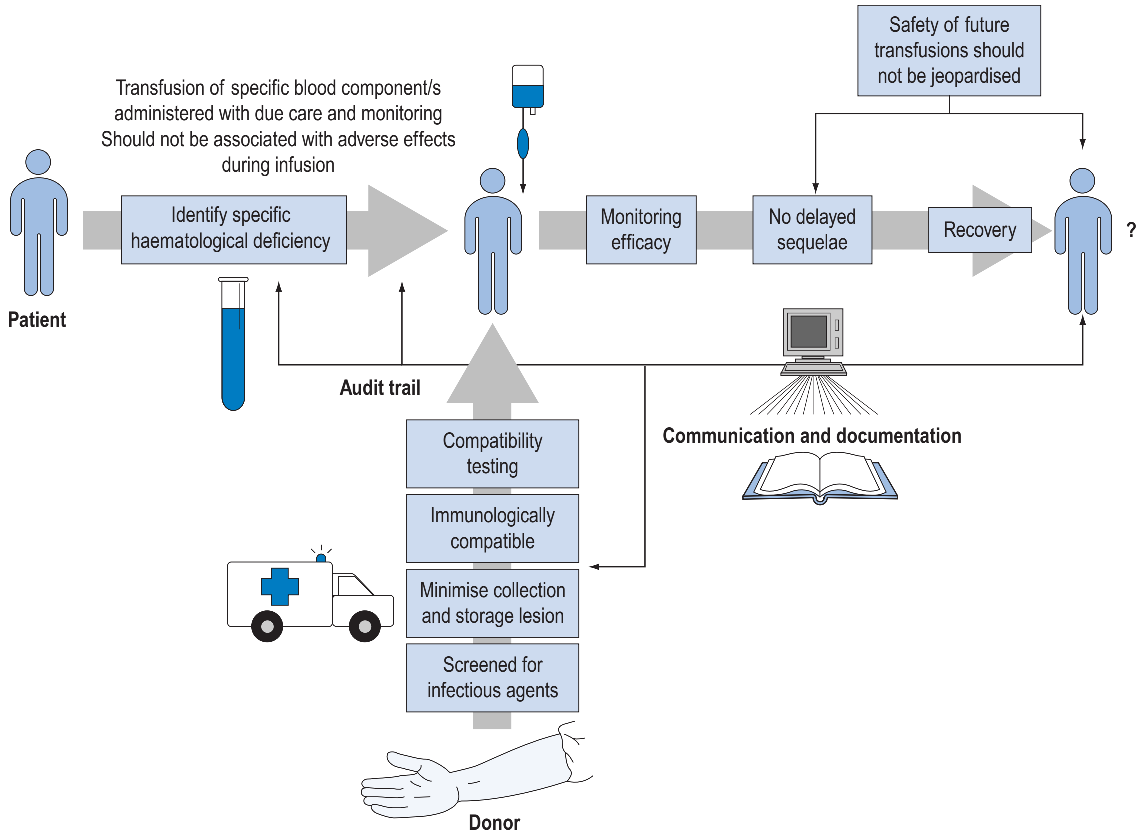

Figure 95.1 What is a safe transfusion?

- Is the patient fully informed of the medical decisions?

Safe and effective transfusion requires attention to the following details (**Fig. 95.1**):

- clearly defined indication and benefits of blood components
- accurate patient identification for blood group compatibility
- identification and careful management of high-risk patients
- appropriate handling, administration and monitoring
- provision of adequate amounts and quality of component(s)
- communication of benefits and risk to the patient/relatives
- the infusion should not be associated with preventable ill effects
- awareness of possible transfusion-related complications
- early diagnosis and prompt action in relation to adverse events of transfusion
- accurate documentation
- input into quality-assurance programmes.

BLOOD STORAGE AND THE STORAGE LESIONS

Blood is altered from the moment of collection and the 'lesions' of collection – anticoagulation, separation, cooling, preservation and storage – compound and progressively increase until the date of expiry.[8] The extent of these changes is determined by collection technique, the specific blood component, the preservative medium, the container, storage time and storage conditions. The threshold storage time for blood components has generally been arbitrarily determined by in vitro studies and assessment of in vivo survival. In the case of red cell concentrates, greater than 75% of transfused cells should survive post transfusion.

Storage results in quantitative and/or qualitative deficiencies in blood components, which may reduce the immediate efficacy of a transfusion. In parallel with these storage changes is an accumulation of degenerate material (e.g. microaggregates and procoagulant material), release of vasoactive agents, cytokine generation and haemolysis.[4] Many of the changes occurring during storage are related to the presence of leucocytes and can be minimised by pre-storage leucoreduction.[9] Red cells undergo a change from their biconcave disc shape to

spiky spherocytes (echinocytes) and in so doing lose their flexibility. There are also changes in the red cell membrane resulting in an increased tendency to adhere to endothelial cell surfaces in the microcirculation, especially if there is activation of endothelial cells, for example in the presence of the systemic inflammatory response (e.g. with shock or sepsis).[10] There is evidence that the immediate post-transfusion function of stored red cells and haemoglobin in delivering oxygen to the microcirculation and unloading is questionable, and several hours are required for red cell oxygen carriage and delivery to return to normal.[11–13] It is important to differentiate between the storage lesion being responsible for failure to achieve clinical/laboratory end-points due to reduced survival and/or qualitative defects in cellular function and the 'toxic' effects of blood storage (**Fig. 95.2**).

The use of blood filters has been an acknowledgement of the existence of the blood storage lesion and its possible clinical significance. The 170 µm blood-giving filters were first introduced into transfusion medicine to stop the occlusion of blood-giving sets. Ironically, there was little concern that the fibrin clots may harm the patient, but fortunately the lung is one of nature's remarkable filters. Adult respiratory distress syndrome (ARDS) and the Vietnam War increased interest in unfiltered microaggregates accumulating during storage. Both logic and animal data suggested their implication in ARDS and that microfilters to remove microparticles 20–40 µm in size may be protective. This proved difficult to confirm, but microaggregate filters do not adequately address the problem of the storage lesion and its clinical significance. Use of pre-storage leucoreduction filters, and prevention of the development of the storage lesion in both blood and platelets from its inception, is more logical and scientific. Universal pre-storage leucoreduction is now standard practice in many countries, although it was primarily introduced as a precautionary measure against the possible transmission of variant Creutzfeldt–Jakob disease (vCJD) and not to address the numerous other indications for the removal of leucocytes.[14]

The clinical significance of blood storage lesions is still controversial. Further studies are needed to assess their relevance in conditions such as ARDS, multi-organ failure (MOF), vasoactive reactions and alterations in laboratory parameters.[15–21] It is assumed that blood components have been appropriately collected, processed, stored, transported and transfused but, despite much greater attention to standard operating procedures and regulation generally, the quality of the final product cannot be guaranteed.[22] The 'assumed' quality of labile cellular blood products is based on research data and monitoring of standard operating procedures. There is rarely detailed individual product assessment prior to transfusion. It is accepted that the adverse effects of storage increase with time and an arbitrary 'cut-off' is mandated on the basis of research studies.

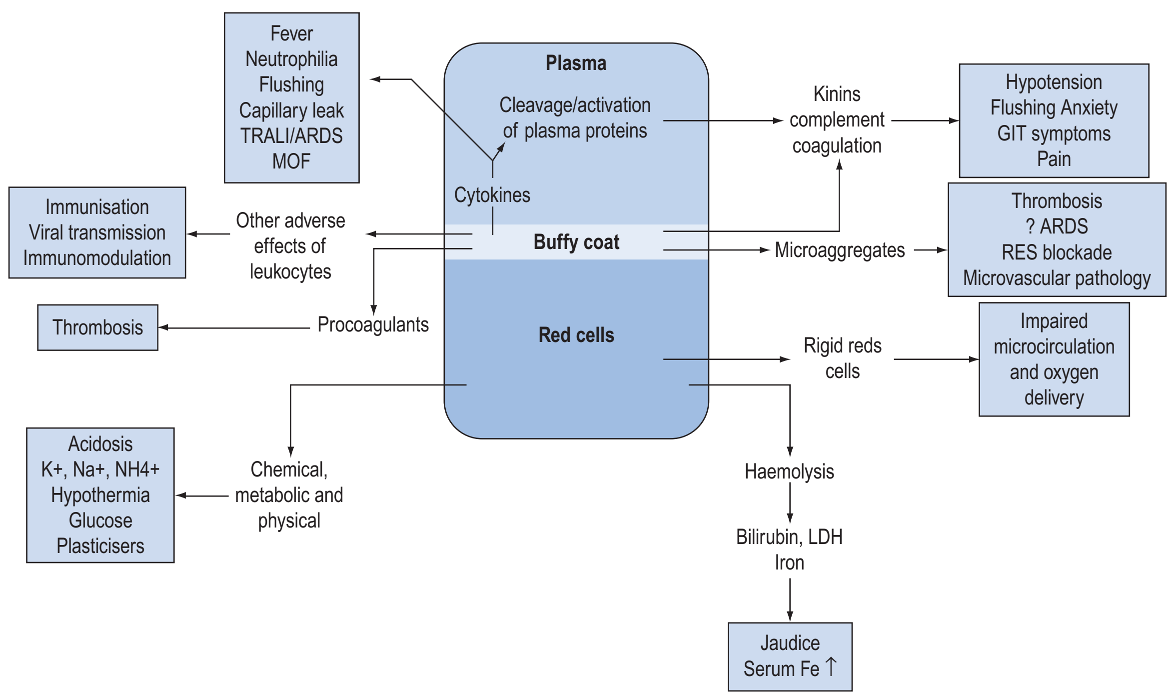

Figure 95.2 The storage lesions. ARDS=adult respiratory distress syndrome; GIT=gastrointestinal tract; MOF=multi-organ failure; RES=reticulo-endothelial system; TRALI=transfusion-related acute lung injury, LDH =lactic dehydrogenase.

In relation to the possible clinical significance of the storage lesion, the following should be considered:

- quantitative and qualitative deficiency of blood component
  - failure to achieve anticipated end-points due to reduced quantity and/or quality of the blood product
  - exposure to excessive numbers of donors in achieving efficacy
- physical characteristics
  - hypothermia
  - chemical characteristics
  - citrate toxicity
  - acid–base imbalance
  - glucose
- contamination
  - bacterial resulting in endotoxaemia or septicaemia
  - plasticisers
- accumulation of 'toxic' or degenerate products
  - role of the storage lesion in transfusion-related immunomodulation
  - role of cytokines
  - role of reticuloendothelial system blockade
  - accentuation of free radical pathophysiology due to free iron
- effects of transfusion on laboratory parameters (e.g. elevations in bilirubin, neutrophils, serum iron and lactic dehydrogenase), which may lead to incorrect interpretation
- large-volume transfusions (proportional to storage age) as a risk factor for MOF and ARDS
- early hyperkalaemia, late hypokalaemia
- activation and consumption of the haemostatic factors with possible contribution to disseminated intravascular coagulation (DIC) and venous thromboembolism
- non-haemolytic, non-febrile transfusion reactions
- hypotension and circulatory instability due to vasoactive substance (kinins, histamine).

THE ROLE OF LEUCOCYTES AS A 'CONTAMINANT' IN LABILE STORED BLOOD AND THE ROLE OF PRE-STORAGE LEUCOREDUCTION

Leucocytes may be responsible for a wide range of blood component quality and safety issues, but there are difficulties in assessing potential adverse effects.[14] Specific adverse outcomes in some patients have been shown to be due to the presence of leucocytes (e.g. non-haemolytic febrile transfusion reaction, platelet refractoriness and transfusion-associated graft-versus-host disease (TAGVHD)), but this is the minority. In the broader context the overall available evidence, in the absence of adequate large randomised clinical trials, suggests that universal pre-storage leucoreduction may reduce transfusion-related morbidity and mortality as well as generating cost savings.[23] Leucoreduction of red cell and platelet concentrates minimises the clinical consequences of the immunomodulatory effects of allogeneic transfusion. Hence it may decrease the incidence of recurrence of some cancers, of postoperative infections and of bloodstream infections and reduce ICU and hospital length of stay. In many patients transfusion-related acute lung injury (TRALI) is a multifactorial disorder and in 'at-risk' patients non-leucoreduced blood may be a risk factor. Patients in whom there is activation of the systemic inflammatory response syndrome (SIRS) are at risk of developing the multi-organ failure syndrome.[24,25] Patients at particular risk include those with trauma, burns, critical bleeding, shock, sepsis and those undergoing cardiopulmonary bypass.[26–29] The quality and function of pre-storage leucoreduced red cell concentrates is better maintained on storage, ensuring better post-transfusion efficacy and survival.[30]

CLINICAL GUIDELINES FOR BLOOD COMPONENT THERAPY

The following is a brief summary of the clinical guidelines for the use of commonly used blood components. The use of specific concentrates or recombinant products is beyond the scope of this book. As alluded to, there is a shift in the current development of clinical practice guidelines from focusing on specific indications for blood components to problem-oriented understanding of the clinical issues (i.e. patient blood management).[31]

RED CELL TRANSFUSIONS

What constitutes appropriate use of red cell transfusions in acute medicine is contentious because of the difficulties in identifying the benefits of red cell transfusion in many circumstances.[32] Pursuit of the lowest safe haematocrit continues to receive considerable attention, but pushing any aspect of a system to its limits risks 'sailing too close to the wind', which may be appropriate in some situations but potentially hazardous in others.[33,34]

In an otherwise stable patient, the transfusion of red cell concentrates is likely to be inappropriate when the haemoglobin level is >100 g/L. On the other hand, their use may be appropriate when haemoglobin is in the range 70–100 g/L if there are other defects in the oxygen transport system, such as cardiorespiratory dysfunction. The decision to transfuse should be supported by the need to relieve clinical signs and symptoms of impaired oxygen transport and prevent morbidity and mortality. The transfusion of red cell concentrates is likely to be appropriate when hemoglobin is <70 g/L

and the anaemia is not reversible with specific therapy in the short term, but lower levels may be acceptable in patients who are asymptomatic, especially in the younger age group.[5]

PLATELET TRANSFUSIONS

Platelet transfusion therapy may benefit patients with platelet deficiency or dysfunction. The following are the indications for platelet transfusions:[35]

PROPHYLAXIS

- Bone marrow failure when the platelet count is $<10\times10^9$/L without associated risk factors for bleeding or $<20\times10^9$/L in the presence of additional risk factors
- To maintain the platelet count at $>50\times10^9$/L in patients undergoing surgery or invasive procedures
- In qualitative platelet function disorders, depending on clinical features and setting (platelet count is not a reliable indicator for transfusion).

BLEEDING PATIENT

- In any haemorrhaging patient in whom thrombocytopenia secondary to marrow failure is considered a contributory factor
- When the platelet count is $<50\times10^9$/L in the context of massive haemorrhage/transfusion and $<100\times10^9$/L in the presence of diffuse microvascular bleeding.

The transfusion of platelet concentrates is not generally considered appropriate:

- when thrombocytopenia is due to immune-mediated destruction
- in thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome
- in uncomplicated cardiac bypass surgery.

FRESH FROZEN PLASMA

There are few specific indications for fresh frozen plasma, but its use may be appropriate:[36]

- for replacement of single-factor deficiencies where a specific or combined factor concentrate is not available
- for treatment of the multiple coagulation deficiencies associated with acute systemic coagulopathies:
  - DIC
  - massive blood transfusion
  - trauma-induced coagulopathy
  - cardiac bypass surgery
  - liver disease
  - peripartum coagulopathies
  - venom-induced coagulopathies
- for treatment of inherited deficiencies of coagulation inhibitors in patients undergoing high-risk procedures where a specific factor concentrate is unavailable
- for immediate reversal of warfarin-induced anticoagulation in the presence of potentially life-threatening bleeding when prothrombin concentrates (PCC) are not available[37] (see Ch. 98).

The use of fresh frozen plasma is generally not considered appropriate in cases of:

- hypovolaemia
- plasma exchange procedures unless post-exchange invasive procedures are planned
- treatment of immunodeficiency states.

CRYOPRECIPITATE

Cryoprecipitate is prepared from freshly collected plasma and contains factor VIII, fibrinogen, von Willebrand factor, factor XIII and fibronectin. Cryoprecipitate was originally developed for treatment of haemophilia due to factor VIII deficiency, but is now prescribed to treat congenital or acquired hypofibrinogenaemia, usually in the context of liver disease, trauma, DIC, hyperfibrinolysis or massive transfusion. Increasingly fibrinogen concentrates are recommended in these clinical settings.

IMMUNOGLOBULIN

Normal human immunoglobulin is available in intramuscular and intravenous forms for the treatment or prevention of infection in patients with proven hypogammaglobulinaemia.[38,39] Intravenous immunoglobulin G has been recommended as adjunctive therapy in patients with fulminant sepsis syndrome, especially those with toxic shock syndrome caused by group A streptococci.[40]

Intravenous immunoglobulin therapy also has a role in therapy of some autoimmune disorders, such as idiopathic thrombocytopenic purpura, autoimmune polyneuropathy and others (see Ch. 97).

FACTOR CONCENTRATES

There is an increasing number of plasma protein concentrates available for clinical use. Some are prepared from donor plasma and some by recombinant technology. Factor VIII and factor IX concentrates have an established role in the management of haemophilia, but others are in the process of establishing their clinical efficacy and indications. Antithrombin III (ATIII) concentrates are available for thrombophilia due to ATIII deficiency and have been recommended in other disorders where ATIII may be depleted (e.g. DIC, MOF) but evidence for efficacy is sparse.[41] Recombinant

human activated protein C has antithrombotic, anti-inflammatory and profibrinolytic properties, but its role in the treatment of patients with severe sepsis remains controversial and it is generally not recommended.[42,43]

Of recent interest is the use of the recombinant activated haemostatic proteins and inhibitors. Recombinant activated factor VII (rFVIIa) was developed for the management of haemophilic patients with coagulation factor inhibitors; rFVIIa is commonly used 'off label' for controlling haemorrhage in the non-haemophilic setting and there is considerable controversy as to its benefits and risks.[44,45] There are an increasing number of case reports and series reporting on the use of rFVIIa in critical life-threatening haemorrhage. Patients with uncontrolled critical bleeding and coagulopathy, despite large transfusions and surgical intervention, have significant mortality rates and rFVIIa in these clinical situations is used as salvage therapy. Its use has been studied in controlled trials where there is critical bleeding in various clinical settings, but evidence for efficacy has been disappointing and thrombotic complications are a potential problem; rFVIIa initiates the extrinsic coagulation pathway when complexed to tissue factors at sites of injury and on activated platelet surfaces.

POTENTIAL ADVERSE EFFECTS OF ALLOGENEIC TRANSFUSION

The pathophysiology of blood transfusion reactions can broadly be divided into five categories (Fig. 95.3):

- Reactions may occur due to *immunological differences* between the donor and recipient, resulting in varying degrees of blood component incompatibility. In general, in order for a reaction to occur, the recipient needs to have been previously immunised to a cellular or plasma antigen.[46]
- A wide range of *infectious agents* may be transmitted by allogeneic blood component therapy.
- *Alterations in blood products due to preservation and storage* may result in quantitative and/or qualitative deficiencies in the blood components, which will reduce transfusion efficacy and expose the patient to potentially adverse consequences from storage accumulants in the component.
- *Technical or clerical errors* may result in adverse events in all the above categories.
- *Psychological* – this includes informed consent issues and patient anxiety about compatibility and infectivity.

In terms of causation of an adverse clinical event, the possible role of blood transfusion can be classified into three categories on the basis of probability[47] (Fig. 95.4):

- *Definite – unifactorial – transfusion caused*: the well-understood and reported hazards of transfusion (i.e. immunological, technical, infectious) are generally unifactorial with a 1:1 causal relationship between the blood component transfused (usually a specific individual unit) and the adverse consequence for the patient. ABO blood group incompatibility, transfusion-related infection transmission, TAGVHD and TRALI due to donor leucoagglutinins are examples in this category.
- *Probable – oligofactorial – transfusion related*: some adverse consequences of transfusion result from interaction with other insults, pathophysiology or host factors, but the contribution of the transfusion can usually be specifically identified. Fever, allergic reactions, hypotensive reactions, pulmonary oedema,

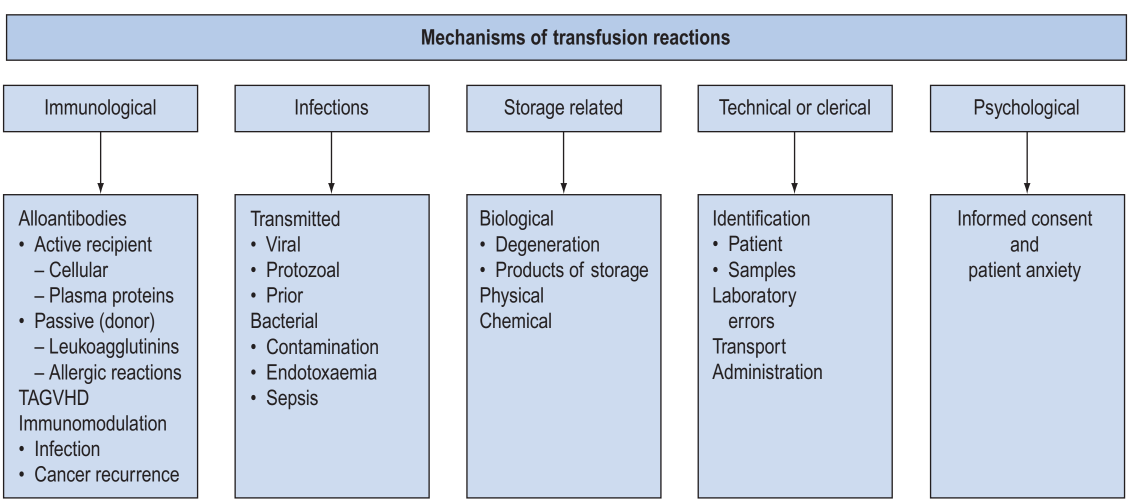

Figure 95.3 Possible mechanisms of adverse effects to blood transfusion. TAGVHD=transfusion-associated graft-versus-host disease.

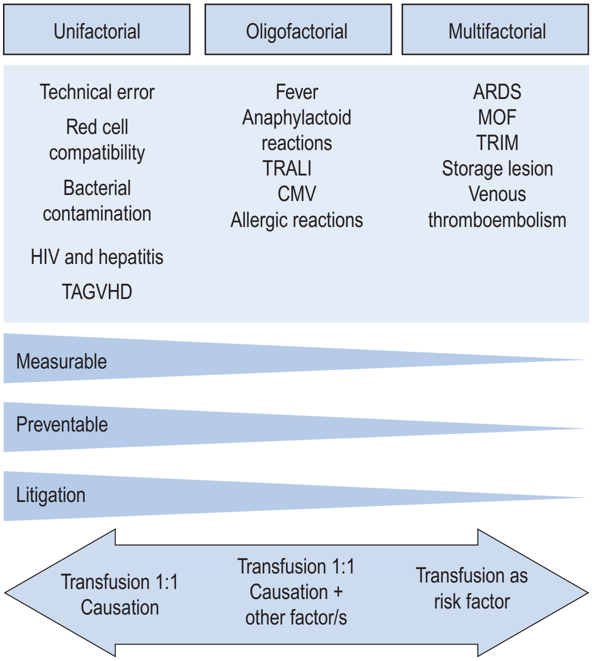

Figure 95.4 Algorithm for analysis for the possibility of a transfusion reaction. ARDS=adult respiratory distress syndrome; CMV=cytomegalovirus; MOF=multi-organ failure; TAGVHD=transfusion-associated graft-versus-host disease; TRIM=transfusion-induced immunomodulation; TRALI=transfusion-related acute lung injury.

some cases of TRALI, hyperbilirubinaemia and cytomegalovirus (CMV) transmission are examples in this category.

- *Possible – multifactorial – transfusion associated*: transfusion may be a contributor to a complication or poor clinical outcome. In these circumstances it may be difficult to implicate transfusion directly in an individual case, nor is it necessarily the major factor. Transfusion-induced immunomodulation (TRIM) and the clinical consequences of storage lesions fall into this category. The role of transfusion being associated with adverse consequences has been established in observational studies, but causation cannot be confidently concluded. Accumulating evidence, in the absence of randomised clinical trials, supports causation, thus demanding a more precautionary approach to allogeneic blood transfusion, examination of alternatives to transfusion and implementation of methods to improve the quality of transfused blood components (especially red cell and platelet concentrates). Universal pre-storage leucoreduction is currently the most important and effective strategy for minimising the clinical impact of TRIM and the blood storage lesions.

Adverse reactions to blood component therapy may present in a wide range of 'guises' and transfusion must always be considered in the differential diagnosis of any unexpected clinical presentation or indeed as a contributory factor to a clinical picture that may have several contributory factors[48] (Fig. 95.5).

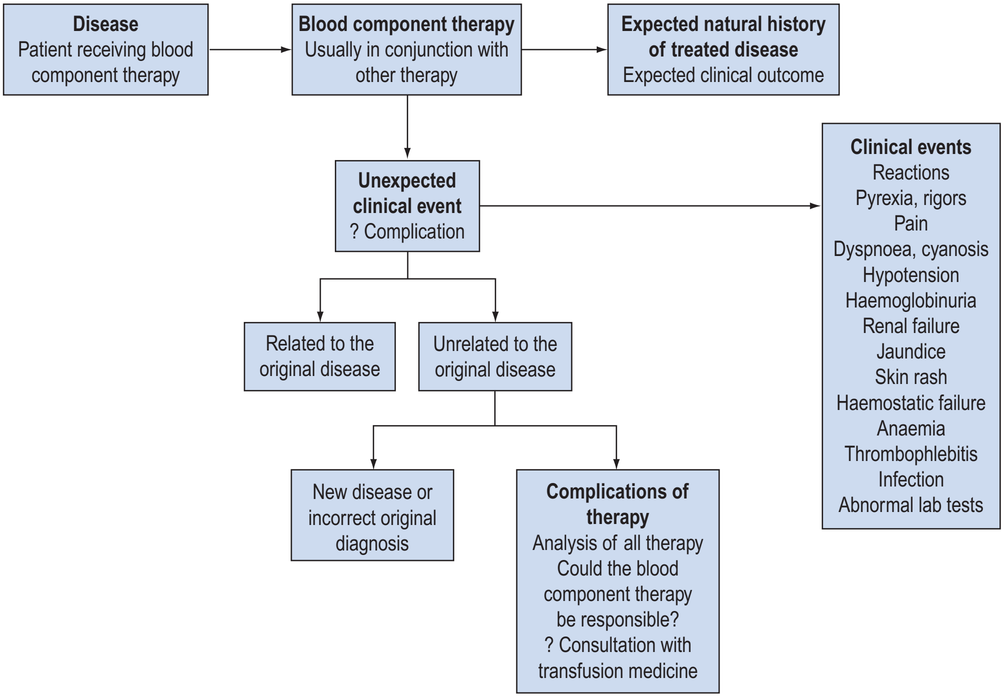

Figure 95.5 Adverse reactions to blood component therapy may just be one of the contributory factors in the differential diagnosis of any unexpected clinical presentation.

PYREXIA

Mild febrile reactions are not usually a matter of concern, but rigors and temperatures above 38°C should not be ignored. The majority of febrile reactions are now considered to be an immunological reaction against one or more of the transfused cellular or plasma components, usually leucocytes.

TRANSFUSION-RELATED INFECTIONS

HEPATITIS

Post-transfusion hepatitis is a potential complication of allogeneic transfusion; donor selection, serological and nucleic acid tests ensure exclusion of infective donors. Hepatitis B and C are now almost totally preventable transfusion-transmitted diseases.

HUMAN IMMUNODEFICIENCY VIRUS

Donor selection, antibody screening and nucleic acid testing of blood donors have almost eliminated transfusion-associated HIV infection.

MONONUCLEOSIS SYNDROMES

The development of swinging pyrexia with varying degrees of peripheral blood atypical mononucleosis, 7–10 days following transfusion, can cause diagnostic confusion. Abnormalities in liver function are common. CMV infection is the commonest cause of this syndrome. When correctly diagnosed CMV is not a serious infection assuming the patient does not have immune compromise.

OTHER TRANSFUSION-TRANSMISSIBLE INFECTIONS

There is an increasing range of agents that have the potential to be transmitted by blood transfusion, the most recent one of concern being vCJD. The reader is referred to reviews for further information.[49]

BACTERIAL CONTAMINATION

Bacterial contamination of stored blood has always been recognised as a potential cause of fulminant endotoxic shock. Although a rare complication, continuing reports of its occurrence, especially in relation to platelet concentrate transfusion, have increased awareness.[50,51] The clinical features of transfusion-related bacterial sepsis in the non-anaesthetised patient include rigors, fever, tachycardia and vascular collapse, with prominent nausea, vomiting and diarrhoea. Anaesthetised patients may have a delayed onset of symptoms (fever, tachycardia, hypotension and cyanosis), followed by DIC, renal failure and sometimes acute lung injury. The requirement to store platelet concentrates at room temperature increases the risks of bacterial contamination. Pre-release bacterial testing is being more widely advocated as a measure to minimise the problem.

HAEMOLYTIC TRANSFUSION REACTIONS

Most severe acute haemolytic transfusion reactions are due to ABO incompatibility, have an identifiable cause and are avoidable, in contrast to delayed haemolytic reactions that are immune in nature and are difficult to prevent.

INITIAL SYMPTOMS AND SIGNS

The classic symptoms and signs of an acute haemolytic transfusion reaction, typical of ABO incompatibility, include apprehension, flushing, pain (e.g. at infusion site, headache, chest, lumbosacral and abdominal), nausea, vomiting, rigors, hypotension and circulatory collapse.

HAEMOSTATIC FAILURE

Haemorrhagic diathesis due to DIC may be a feature, resulting in severe generalised haemostatic failure, with haemorrhage and oozing from multiple sites.[52] As the responsible transfusion is likely to have been administered for haemorrhage, increasing severity of local bleeding may be the first clue to an incompatible transfusion, especially if the patient is unconscious or anaesthetised in the operating room.

OLIGURIA AND RENAL IMPAIRMENT

Renal impairment may complicate a haemolytic transfusion reaction and its prevention or the appropriate management of established renal failure is important. If circulating volume and urinary output are rapidly restored, established renal failure is unlikely to occur. Death from acute renal failure directly caused by an incompatible blood transfusion is preventable, and there are usually other poor prognostic factors.

ANAEMIA AND JAUNDICE

A severe haemolytic transfusion reaction may be suspected from the development of jaundice or anaemia.

ALLERGIC AND ANAPHYLACTOID REACTIONS

Non-cellular blood (plasma and plasma derivatives) components are rarely considered to be a major cause for adverse reactions to transfusion therapy. However, the complexity of plasma and its various components and the effects from component processing results in a broader spectrum of potential adverse effects than is frequently recognised. The antigenic heterogeneity of plasma proteins and the presence of antibodies make the non-cellular components of blood responsible for a range of adverse effects, many of which remain poorly understood and commonly pass unrecognised in clinical practice.[53]

There has been debate over the years as to the classification of allergic reactions to blood components. Clinical severity may range from minor urticarial reactions or flushing through to fulminant cardiorespiratory collapse and death. Some of these reactions are

probably true anaphylaxis, but in others the mechanisms have been less clear and the term 'anaphylactoid' has been used. To avoid implying the mechanism of the reaction, the term 'immediate generalised reaction' has also been used.

The clinical syndromes of immediate reactions have been classified as follows:

- *Grade I:*
  - skin manifestations
- *Grade II:*
  - mild to moderate hypotension
  - gastrointestinal disturbances (nausea)
  - respiratory distress
- *Grade III:*
  - severe hypotension, shock
  - bronchospasm
- *Grade IV:*
  - cardiac and/or respiratory arrest.

PLASMA AND PLASMA COMPONENTS MAY CAUSE ADVERSE EFFECTS BY SEVERAL PATHOPHYSIOLOGICAL MECHANISMS

Immunological reactions to normal components of plasma may occur in two ways:

- plasma proteins being antigenic to the recipient; they may contain epitopes on their molecules different from those on the recipient's functionally identical plasma proteins (e.g. anti-IgA antibodies)
- antibodies in the donor plasma reacting with cellular components of the recipient's blood cells or plasma proteins.

Physicochemical characteristics and contaminants of donor plasma, such as temperature, chemical additives, medications and micro-organisms, may be responsible for recipient reactions.

The preparation techniques and storage conditions of blood and blood products may potentially cause adverse reaction through:

- *accumulation of metabolites* or cellular release products
- *plasma activation* (i.e. activation of some of the proteolytic systems). Importantly, the complement and kinin/kininogen systems may generate vasoactive substances and anaphylatoxins which may be responsible for reactions. Some apparently allergic reactions to blood products may be due to vasoactive substances in the infusion. Subjective sensations may be missed in an unconscious patient. Hypotension occurring during rapid infusion of a hypovolaemic patient is likely to be interpreted as further volume loss, particularly with some plasma protein fractions that have been reported as consistently producing a transient fall in blood pressure, and a situation fraught with risk of overload can be produced
- *histamine generation*: histamine levels increase in some stored blood components and levels may be correlated with non-febrile, non-haemolytic transfusion reactions. Histamine release may be stimulated in the patient by plasma components, synthetic colloids and various medications
- *generation of cytokines* during storage may be responsible for non-haemolytic transfusion reactions
- *chemical additives*: there are various chemical additives (ethylene oxide, formaldehyde, drugs, latex) that may be responsible for immunological or non-immunological recipient reactions.

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE (TAGVHD)

Graft-versus-host disease, classically observed in relationship to allogeneic bone marrow transplantation, may occur following a blood transfusion owing to the infusion of immunocompetent lymphocytes precipitating an immunological reaction against the host tissues of the recipient.[54] It is most commonly observed in immunocompromised patients, but may also be seen in recipients of directed blood donation from first-degree relatives, and occasionally where donor and recipient are not related, owing to homozygosity for HLA haplotypes for which the recipient is heterozygous. The syndrome usually occurs 3–30 days post allogeneic transfusion with fever, liver function test abnormalities, profuse watery diarrhoea, erythematous skin rash and progressive pancytopenia. Gamma irradiation of blood products is currently the standard of care for the prevention of TAGVHD.[55]

TRANSFUSION-RELATED ACUTE LUNG INJURY (TRALI)

TRALI is receiving a great deal of attention as a potentially serious complication of blood transfusion.[56] In the classic plasma neutrophil antibody-mediated form of the disease, symptoms usually arise within hours of a blood transfusion.[57] In contrast to most patients with ARDS, recovery usually occurs within 48 hours. The underlying pathophysiology of 'classic' TRALI is due to the presence of leucoagglutinins in donor plasma. When complement is activated, C5a promotes neutrophil aggregation and sequestration in the microcirculation of the lung, causing endothelial damage leading to an interstitial oedema and acute respiratory failure. This classic form of transfusion-related acute lung injury has been recognised for over five decades, but was thought to be a rare complication of allogeneic plasma transfusion. As leucoagglutinins occur typically in plasma from multiparous females there is a move to using male-donor-only fresh frozen plasma.

It is now accepted that there has been under-recognition and underdiagnosis of TRALI, due partly to a lack of clinical awareness, but also to a broader

understanding of mechanisms by which blood transfusion may cause or be a contributory factor to lung injury.[58,59] The term 'TRALI' is now being expanded to include cases in which transfusion is identified as an independent risk factor predisposing patients to lung injury. The reader is referred to recent reviews addressing the expanding area of concern in which transfusion, per se, is being identified as an independent risk factor for poor clinical outcomes, of which TRALI is only one.[47] There is also recent experimental evidence supporting a 'two-hit' hypothesis in which patients may be 'primed' by shock, sepsis or extracorporeal circulation making them more susceptible to acute lung injury from blood transfusion.[60]

TRANSFUSION-RELATED IMMUNOMODULATION (TRIM)

Allogeneic blood transfusion is immunosuppressive having implications in relation to resistance to infection and the likelihood of cancer recurrence.[61–63] Donor leucocytes probably play the most important role in this immunomodulation. TRIM, along with the clinical effects of the blood storage lesion, is probably the mechanism by which allogeneic blood transfusion is responsible for poorer clinical outcomes discussed in the next section.

ALLOGENEIC TRANSFUSION AS AN INDEPENDENT RISK FACTOR FOR POORER CLINICAL OUTCOMES

Over the last decade experimental and clinical studies have identified blood transfusion as an independent risk factor for morbidity and mortality as well as increased admission rates to ICUs, assisted ventilation, increased length of hospital stay and additional costs.[64,47,65,66] Blood transfusion being implicated as part of the problem rather than optimal therapy has been a surprise to many clinicians, health administrators and patients, as it has always been assumed that blood transfusion can only be of benefit to the bleeding or anaemic patient. This long-standing belief is now being effectively challenged and currently the debate on the management of the acutely haemorrhaging or anaemic patient has moved significantly from a paradigm with a focus on transfusion to one in which the urgent control of critical bleeding is the paramount priority, with avoidance and/or minimisation of blood transfusion. There is thus increasing evidence that transfusion-related immunomodulation (TRIM) and the transfusion effects of storage lesions, especially with older stored blood, are responsible for poorer clinical outcomes in a range of clinical settings.[67–72]

However, it is not possible to categorically conclude causation and that pre-storage leucoreduction will eliminate or minimise the risk. Although the case for causation is strengthening, it is important to be aware that there is minimal evidence for the efficacy or appropriateness of many transfusions, and there is evidence that restrictive red cell transfusion policies do not jeopardise clinical outcomes in haemodynamically stable patients; indeed, the reverse may be the case.[73–75] Thus, until these issues are resolved, a precautionary approach should be adopted, with the modus operandi being to avoid or minimise allogeneic transfusion and use appropriate patient blood management techniques.[2,34,76] Additionally there is an association with transfusion and a higher incidence of venous thromboembolism.[77,78]

CRITICAL HAEMORRHAGE AND MASSIVE BLOOD TRANSFUSION

There is a reappraisal of clinical practice guidelines for the use of blood components in the bleeding patient.[79–81] The guidelines are no longer for the management of massive blood transfusion, but rather for the management of critical bleeding and avoiding getting into the massive transfusion coagulopathy quagmire in which the patient can spiral down into the 'triad of death'– coagulopathy, acidosis and hypothermia.

This reappraisal of management of patients with acute haemorrhage is resulting in the challenging of long-standing dogmas. There is greater tolerance of hypotension until haemorrhage is controlled, and lower haemoglobin levels are tolerated with closer attention to the clinical context of the anaemia and its impact on systemic and local oxygen delivery, especially if there are any compromises in cardiorespiratory function. More attention and research are being directed toward the role of clear fluids and the importance of plasma viscosity, colloid oncotic pressure and functional capillary density.[69] The search for safe and more effective plasma substitutes and haemoglobin-based oxygen carriers continues.[82]

If blood loss has been massive or there are defects in the haemostatic system, specific component therapy may be indicated. Advances in patient retrieval, resuscitation protocols, techniques for rapid and real-time diagnosis, trauma teams and early 'damage control' surgery have improved the management of acutely haemorrhaging patients. Patients are now surviving with larger volumes of blood transfusion, but sepsis, acute lung injury and multi-organ failure remain major challenges, and blood transfusion is increasingly being recognised as a two-edged sword and probably a contributory factor to these complications in which microcirculatory dysfunction and impaired tissue cellular metabolism are recognised as important in the pathophysiology. As already discussed, the evidence that the immediate post-transfusion ability of stored red cells and haemoglobin to deliver and unload oxygen to the microcirculation may be impaired is resulting in stored red cell concentrates not being automatically the first therapy for acutely enhancing oxygen delivery. Indeed,

recent animal data indicate that the immediate clinical benefit of transfused red cells in treating hypovolaemic shock relates to reconstitution of the macrocirculation, with adverse effects on the functional capillary density in the microcirculation.[83] Concerns around the storage age of blood at the time of transfusion are now receiving considerable attention with impressive observational and mechanistic evidence pointing towards the likelihood that blood less than 2 weeks old will be optimal. If results of RCTs confirm this to be so then there will be significant challenges for the blood sector in supply chain management.

In previously healthy patients who have suffered an acute blood loss of less than 25% of their blood volume, restoring that volume is more important than replacing oxygen-carrying capacity. Plasma volume expanders may preclude the necessity for allogeneic transfusion, especially if bleeding can be controlled. Clear fluids also allow time for transfusion compatibility testing. In the context of acute bleeding and hypovolaemic shock, the haemoglobin level is not the primary indicator for determining the need for allogeneic red cell transfusion. A normal human may survive a 30% deficit in blood volume without fluid replacement, in contrast to an 80% loss of red cell mass if normovolaemia is maintained. Minimisation of allogeneic blood transfusion is important and haemodilution with tolerance of anaemia is now accepted clinical practice. However, there are limits to haemodilution, not only from the perspective of oxygen-carrying capacity. Marked reduction in blood viscosity is counterproductive as reactive peripheral vasoconstriction to maintain total peripheral resistance results in reduction in functional capillary density in the microcirculation. The role of clear fluids and the importance of plasma viscosity, colloid oncotic pressure, electrolyte composition and functional capillary density are the subject of current research.[84]

A protocol approach to blood component therapy is generally not recommended, as each patient should be treated individually. However, this remains a controversial issue with advocates for 'blind', up-front component therapy with red cell and haemostatic components, especially fresh frozen plasma and cryoprecipitate or fibrinogen concentrates. There are also enthusiastic advocates for 1:1:1 (red cells, platelets, plasma) replacement protocols based on recent military experience and this is recommended in some critical-bleeding protocols.

Many hospitals now have massive transfusion protocols that are activated on the basis of specific criteria. With better understanding of coagulopathy in the critical haemorrhage setting and the importance of hypofibrinogenaemia and hyperfibrinolysis, there is a reanalysis of the approach to blood component therapy.[85–87] In an elective situation in which normovolaemia is generally maintained from the outset, defects can be predicted and appropriate blood components prescribed, a protocol approach may be justified. This should be done in close consultation with the haematologist and hospital transfusion service.

Failure of haemostasis is common in critically bleeding patients and may be complex and multifactorial in pathogenesis.[85] The importance of avoiding acidosis and hypothermia cannot be overemphasised as the triad of coagulopathy, acidosis and hypothermia has an extremely poor prognosis. Coagulopathy associated with critical haemorrhage is related to other aspects of the pathophysiology of the clinical setting. The assumption that there is a 'generic coagulopathy' vaguely referred to as DIC is incorrect and can result in inappropriate therapeutic decisions. The reader is referred to an expanding literature on this topic where it will be seen that there can be no standard approach to therapy.[77] This author is increasingly convinced that the pathophysiology of coagulopathy, when occurring in the context of critical haemorrhage, should be viewed as related to the primary insult/initiating event, and that a 'secondary' coagulopathy (e.g. massive stored blood transfusion, haemodilution, hypothermia, continuing tissue hypoxia, etc.) may compound the problem in the resuscitated patient. The primary mechanisms of coagulopathy relating to the initiating event may relate to trauma, hypoxia, pregnancy, microbial infection, envenomation or iatrogenic (antithrombotic) agents. In all circumstances there is activation or inhibition of some aspect of the haemostatic system, and therapy is better informed if the varied mechanisms are understood. Frequently, complex tests are required for definitive diagnosis, but the urgency of the situation cannot always await the results, and therapy may be initiated on clinical evidence with minimal laboratory information.

Many trauma patients have coagulopathy at presentation that is related more to hypovolaemic shock and not to consumption or dilution. Excessive activation of the protein C system and hypofibrinogenaemia secondary to secondary hyperfibrinolysis are important.[86,87] Except for severe abnormalities, haemostatic laboratory parameters correlate poorly with clinical evidence of haemostatic failure. In the massively transfused patient, thrombocytopenia and impaired platelet function are the most consistent significant haematological abnormalities, correction of which may be associated with control of microvascular bleeding. Coagulation deficiency from massive blood loss is initially confined to factors V and VIII. Activated partial thromboplastin time (APTT), prothrombin time (PT) and fibrinogen assay should be performed, but the urgency of the situation does not usually allow for other specific factor assays. Fibrinogen, the bulk protein of the haemostatic system and essential for effective fibrin clot formation, is receiving greater attention with wider recommendations for replacement using concentrates or cryoprecipitate.

A problem with the standard screening tests of coagulation function is that they do not give information

about the actual formation of the haemostatic plug, its size, structure or stability. For this reason there is increasing interest in global tests of haemostatic plug formation and stability such as thromboelastography, thrombin generation tests and clot waveform analysis in which changes in light transmission in routine APTT are measured. Fresh frozen plasma should be infused if the test results are abnormal, including cryoprecipitate or fibrinogen concentrates in the presence of hypofibrinogenaemia. Fibrinogen levels <1 g/L have generally been the trigger for replacement, but this is being reassessed, especially in the peripartum setting.[88,89]

With ongoing bleeding with associated microvascular oozing, various approaches may be taken. Having ensured that all identifiable haemostatic defects have been corrected, questions arise as to the role of fresh blood and, more recently, recombinant activated factor VII (rFVIIa).[45,90] The use of freshly collected whole blood remains controversial and is an 'emotive' subject needing some comment, but is advocated in the military setting. The provision of fresh whole blood can present logistic, ethical and safety problems needing consideration. Many transfusion medicine specialists categorically state that there is never an indication for fresh whole blood. Such dogma can be difficult to defend in the clinical setting of the massive haemorrhage and transfusion syndrome where pathophysiology remains poorly understood and specific blood component therapy may be ineffective.

The following statements reasonably summarise the current status of fresh blood transfusion:

- fresh blood provides immediately functioning oxygen-carrying capacity, volume and haemostatic factors in the one product
- the number of allogeneic donors to whom a patient is exposed is reduced
- problems associated with infusion of massive volumes of stored blood can be minimised/avoided
- the risk of transfusion-related viral infections is possibly higher than fully tested and stored blood.

SPECIFIC HAZARDS OF MASSIVE BLOOD TRANSFUSION

Massive blood transfusion may be defined in several ways:

- replacement of the circulating volume in 24 hours
- >4 units of blood in 1 hour with continuing blood loss
- loss of 50% of circulating blood volume within 3–4 hours.

Any patient receiving massive blood component therapy is likely to be seriously ill and have multiple problems. Many adverse effects must be considered in conjunction with the injuries and multi-organ dysfunction. It is not always possible to define the complications caused or aggravated by massive blood transfusion.

CITRATE TOXICITY

A patient responds to citrate infusion by the removal of citrate and mobilisation of ionised calcium. Citrate is metabolised by the Krebs cycle in all nucleated cells, especially the liver. A marked elevation in the citrate concentration is seen with transfusion exceeding 500 mL in 5 minutes; the level rapidly falls when the infusion is slowed. Citrate metabolism is impaired by hypotension, hypovolaemia, hypothermia and liver disease. Toxicity may also be potentiated by alkalosis, hyperkalaemia, hypothermia and cardiac disease. The clinical significance of a minor depression of ionised calcium remains ill defined, and it is accepted that a warm, well-perfused adult patient with normal liver function can tolerate a unit of blood each 5 minutes without requiring calcium. The rate of transfusion is more significant than the total volume transfused. Common practice is to administer 10% calcium gluconate 1.0 g i.v. following each 5 units of blood or fresh frozen plasma. Such a practice remains controversial as there is concern regarding calcium homeostasis and cell function in acutely ill patients.

ACID–BASE AND ELECTROLYTE DISTURBANCES

Acid–base

Stored bank blood contains an appreciable acid load and is often used in a situation of pre-existing or continuing metabolic acidosis. The acidity of stored blood is mainly due to the citric acid of the anticoagulant and the lactic acid generated during storage. Their intermediary metabolites are rapidly metabolised with adequate tissue perfusion, resulting in a metabolic alkalosis. Hence the routine use of sodium bicarbonate is usually unnecessary and is generally contraindicated. Alkali further shifts the oxygen dissociation curve to the left, provides a large additional sodium load and depresses the return of ionised calcium to normal following citrate infusion. Acid–base estimations should be performed and corrected in the context of the clinical situation. With continuing hypoperfusion, however, metabolism of citrate and lactate will be depressed, lactic acid production will continue and there may be an indication for i.v. bicarbonate and calcium to correct acidosis and low ionised calcium.

Serum potassium

Although controversial, it is unlikely that the high serum potassium levels in stored blood have pathological effects in adults, except in the presence of acute renal failure. However, hypokalaemia may be a problem 24 hours after transfusion as the transfused cells correct their electrolyte composition and potassium returns into the cells. Thus, although initial acidosis and hyperkalaemia may be an immediate problem with massive blood transfusion, the net result of successful resuscitation is

likely to be delayed hypokalaemia and alkalosis. With CPD (citrate–phosphate–dextrose) blood, the acid load and red cell storage lesion are less. Constant monitoring of the acid–base and electrolyte status is essential in such fluctuating clinical situations.

Serum sodium

The sodium content of whole blood and fresh frozen plasma is higher than the normal blood level due to the sodium citrate. This should be remembered when large volumes of plasma are being infused into patients who have disordered salt and water handling (e.g. in renal, liver or cardiac disease).

HYPOTHERMIA

Blood warmed from 4°C to 37°C requires 1255 kJ (300 kcal) – the equivalent heat produced by 1 hour of muscular work – with an oxygen requirement of 62 L. Hypothermia impairs the metabolism of citrate and lactate, shifts the oxygen dissociation curve to the left, increases intracellular potassium release, impairs red cell deformability, delays drug metabolism, masks clinical signs, increases the incidence of arrhythmias, reduces cardiac output and impairs haemostatic function. Thus a thermostatically controlled blood-warming device should be routinely used when any transfusion episode requires the rapid infusion of more than 2 units of blood.

HYPERBILIRUBINAEMIA

Jaundice is common following massive blood transfusion as a significant amount of transfused stored blood may not survive, resulting in varying degrees of hyperbilirubinaemia. During hypovolaemia and shock, liver function may be impaired, particularly in the presence of sepsis or multi-organ failure. An important rate-limiting step in bilirubin transport is the energy-requiring process of transporting conjugated bilirubin from the hepatocyte to the biliary canaliculus. Thus, although an increased load of bilirubin from destroyed transfused red cells may be conjugated, there may be delayed excretion leading to a conjugated hyperbilirubinaemia. This ‘paradoxical’ conjugated hyperbilirubinaemia may be misinterpreted, leading to unnecessary investigations. The effect of resorbing haematoma and the possibility of an occult haemolytic transfusion reaction should also be considered.

BASIC IMMUNOHAEMATOLOGY

Red cell serology is a highly specialised area of knowledge and it is not possible to expect clinicians to have more than a basic working knowledge essential for patient safety. The following is a summary of core knowledge for the clinician.

SALINE AGGLUTINATION

Safe red cell transfusion has revolved around this traditional serological technique. A saline suspension of red cells is mixed with serum and observed for agglutination. Saline agglutination is used for ABO blood grouping and is one of the techniques for compatibility testing of donor blood.

THE DIRECT AND INDIRECT ANTIGLOBULIN TEST

In red cell serology, the antiglobulin test (Coombs test) is used to detect IgG immunoglobulins or complement components. The direct antiglobulin test (DAT) detects immunoglobulin or complement components present on the surface of the red cells circulating in the patient. The result is positive in autoimmune haemolytic anaemia and haemolytic disease of the newborn and during a haemolytic transfusion reaction. The indirect antiglobulin test (IAT) detects the presence of non-agglutinating antibodies in the patient’s plasma, usually IgG type. Antibody screening for atypical antibodies and pre-transfusion compatibility testing are the main applications of the IAT.

REGULAR AND IRREGULAR (ATYPICAL) ANTIBODIES

The regular alloantibodies (isoagglutinins) of the ABO system are naturally occurring agglutinins present in all ABO types (except AB), depending on the ABO group. Group O people have anti-A and anti-B isoagglutinins, group A have anti-B and Group B have anti-A. Group A cells are the cause of the commonest and most dangerous ABO-incompatible haemolytic reactions. Atypical antibodies are not normally present in the plasma, but may be found in some people as naturally occurring antibodies or as immune antibodies. Immune antibodies result from previous exposure due to blood transfusion or pregnancy. Naturally occurring antibodies more frequently react by saline agglutination and, although they may be stimulated by transfusion, are usually of minimal clinical significance. In contrast, many of the immune atypical antibodies are of major clinical significance and their recognition is the raison d’étre for pre-transfusion compatibility testing and antenatal antibody screening. Most of the clinically significant immune atypical antibodies are detected by the IAT.

Blood group antigens vary widely in their frequency and immunogenicity. The D antigen of the Rhesus blood group system is common and highly immunogenic. Thus, when a Rh-negative (i.e. D-negative) patient is exposed to D-positive blood there is a high likelihood of forming an anti-D antibody. It is for this reason that the D antigen is taken into account when providing blood for transfusion, in contrast to the numerous other red cell antigens that are less common or less immunogenic. Beyond the Rh (D), and sometimes the Kell (K) blood group antigens, it is not practical, or necessary, to take notice of other blood group antigens unless an atypical antibody is detected during antibody-screening procedures.

THE ANTIBODY SCREEN

On receipt of a blood sample by the transfusion service, the red cells are ABO and Rh D typed and the serum is screened for atypical antibodies. This screen consists of testing the patient's serum with group O screening cells. The screening panel consists of red cells obtained usually from two group O donors containing all common red cell antigens occurring with a frequency of greater than approximately 2% in the community. If an atypical antibody is detected on the antibody screen, further serological investigations are carried out to identify the specificity of the antibody. These investigations are time-consuming and when possible should be carried out electively.

THE CROSSMATCH (COMPATIBILITY TEST)

The crossmatch is the final compatibility test between the donor cells and the patient's serum. The crossmatch test tends to be overemphasised, to the detriment of the antibody screen. With sophisticated knowledge of serology the emphasis in the supply of compatible blood is now concentrated on the steps prior to the final compatibility crossmatch.

THE TYPE AND SCREEN SYSTEM

As pre-compatibility testing has assumed the major role in the selection of blood for transfusion, there has been a rethinking of policies relating to the supply of blood for elective transfusions. Whenever elective surgery is planned for a patient who is likely to require blood transfusion, the transfusion service must receive a clotted blood sample well before the anticipated time of surgery. The pre-compatibility testing should be carried out during the routine working hours when facilities are geared for large workloads and enough staff is available to handle all contingencies.

THE PROVISION OF BLOOD IN EMERGENCIES

When quick clinical and laboratory decisions are made under conditions of stress it is frequently difficult for all involved personnel to appreciate the difficulties of others. The decision to give uncrossmatched, partially crossmatched or wait for crossmatched compatible blood is not easy, and certain basic serological considerations may clarify for the clinician some of the problems faced by the serologist. Depending upon the degree of urgency and the extent of previous knowledge about the patient's red cell serology, blood can be provided with varying degrees of safety. However, it should be emphasised that when a patient is exsanguinating and likely to die, the giving of ABO-compatible uncrossmatched blood, especially if the antibody screen is negative, is safe and appropriate therapy.

UNIVERSAL DONOR GROUP O BLOOD

Group O blood under normal circumstances will be ABO compatible with all recipients. The transfusions should be given as red cell concentrates screened for high-titre A or B haemolysins and used only in extreme emergencies. If the recipient is of childbearing age, every attempt should be made to give Rh-D-negative blood until the patient's blood group is known.

ABO-GROUP-SPECIFIC BLOOD

Transfusion of blood of the correct ABO type circumvents the isoagglutinin problems alluded to above. Simple as this approach may seem, its safety is dependent on meticulous attention to grouping. Previous blood group information, such as a 'bracelet' group or 'unofficial' group written in the patient's records, may be incorrect and there may be considerable risk if blood is administered on the basis of this information.

SALINE-COMPATIBLE BLOOD

The administration of saline-compatible blood is, for practical purposes, the administration of ABO-group-specific blood.

Colloids and blood products

Michael MG Mythen and Matthias Jacob

Colloids are used to maintain or restore deficits in blood volume. Hydrostatic and osmotic forces dictate movement of fluid between the different compartments of the body across semipermeable membranes, a phenomenon that is traditionally called Starling's principle within the circulatory system. Recently, the glycocalyx, an additional structure, is now thought to be crucial for a properly working vascular barrier.[1] It consists of membrane-bound proteoglycans and glycosaminoglycans with negatively charged side chains binding plasma proteins. Only an intact endothelial surface layer (ESL) guarantees a physiological vascular barrier, generating an inwardly directed oncotic gradient only across the protein-loaded ESL layer and a small, protein-free space directly beneath, completely at the luminal side of the endothelial cell line (**Fig. 96.1**). The traditionally presumed gradient across the anatomical vessel wall appears to be of minor importance. The ESL, and therefore vascular barrier competence, is endangered by many noxas common in critical illness and major surgery (e.g. inflammation, trauma, ischaemia/reperfusion injury and hypervolaemia). If the barrier is working, the intravascular osmotic pressure is an important determinant of the amount of intravascularly bound extracellular fluid and, therefore, of the quantitative component of cardiac preload, the target of colloidal infusion measures.

The osmotic pressure generated by a solute is proportional to the number of molecules or ions and independent of molecular size.

Colloid osmotic pressure (COP) is that exerted by macromolecules (proteins and colloids).[2,3] It can be measured using a membrane transducer system in which the membrane is freely permeable to small ions and water but largely impermeable to the colloid molecules.[4] The membrane pore size and the molecular size distribution of the colloid being studied will dictate the measured value (**Figs 96.2** and **96.3**).[3,4] The intact vascular barrier is freely permeable to electrolytes and other small osmolytes (glucose, mannitol), but relatively impermeable to macromolecules (see Fig. 96.3). An iso-oncotic colloid or protein preparation is a non-crystalline substance consisting of those macromolecules, the oncotic pressure being equal to that of the human plasma.

These types of fluid should theoretically, when infused into the intravascular space, expand the pre-existing blood volume by the volume infused – that is, the so-called volume effect should be around 100%.[4,5] Meanwhile, it has become evident that this is not inevitably true for all situations in vivo; colloidal volume effects are context sensitive.[6] It could be demonstrated in human patients that close to 100% of an iso-oncotic preparation of human albumin or hydroxyethylstarch remains within the circulatory compartment when infused to maintain normovolaemia during acute blood loss. When infused into a normovolaemic circulatory compartment, the volume effect comes down towards 40%, the rest directly shifting towards the interstitial space causing a marked alteration of the ESL.[7] The mechanism behind this might be the release of atrial natriuretic peptide-activating metalloproteases, which digest the endothelial glycocalyx. Accordingly, avoiding hypervolaemia might be an advantage in patients undergoing major surgery.

Crystalloids have larger volumes of distribution depending on their composition[8] (**Fig. 96.4** and **Table 96.1**). Whereas isotonic solutions target the whole extracellular compartment, hypotonic preparations additionally load the intracellular space. Colloids or plasma substitutes initially target the intravascular compartment. Ideal properties include:

- stable with a long shelf life
- pyrogen, antigen and toxin free
- free from risk of disease transmission
- intravascular volume effect lasts for several hours
- metabolism and excretion do not adversely effect the recipient
- no tissue storage
- no direct adverse effects (e.g. causing a coagulopathy).

COLLOID SOLUTIONS

There are two major groups of colloids: plasma derivatives and semisynthetics.[1] Plasma derivatives include human albumin, plasma protein fraction, fresh frozen plasma and immunoglobulin solutions. Three principal types of semisynthetic colloids are commonly used in

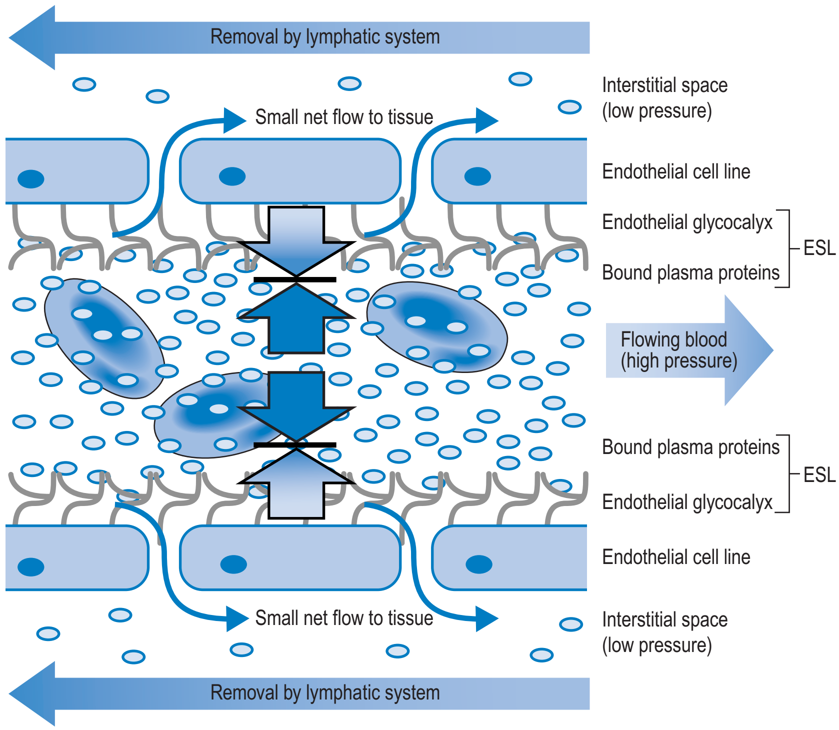

Figure 96.1 The role of the endothelial surface layer (ESL) for fluid homeostasis in steady state: an inwardly directed oncotic gradient across the ESL (orange arrows) opposes the hydrostatic force towards the interstitial space (thick black arrows). The net result is only a small fluid flux (thin black arrows), which is removed by the lymphatic system.

intravenous solutions: gelatins, dextrans and hydroxyethyl starches. All colloids are presented dissolved in a crystalloid solution, isotonic saline still being the most common one, but isotonic glucose, hypertonic saline and isotonic balanced electrolyte solutions are also used.

Whereas human albumin solution contains more than 95% albumin with a uniform molecular size (monodispersity), all the semisynthetic colloids have a distribution of molecular sizes (polydispersity).[3,4] The size–weight relationship is relatively constant although some colloids can have equivalent molecular weight

(MW) with different molecular size – succinylated and urea-linked gelatins have almost identical molecular weights but the succinylated product undergoes conformational change due to an increase in negative charge and is physically larger.[4,5]

HUMAN ALBUMIN SOLUTION

Naturally occurring human albumin is thought of as an ideal colloid and is commonly the reference solution against which other colloids are judged; solutions are prepared from human plasma and heat treated to ensure that neither hepatitis nor HIV can be transmitted. It has a relatively short (~1 year) shelf life at room temperature, but a 5-year shelf life at 2–8°C. Human albumin 5% (the 4% version is a cost-free by-product of the production of packed red cells, exclusively used in Australia) is used for the treatment of hypovolaemia in a wide variety of clinical conditions. Concentrated salt-poor 20% human albumin is used for the treatment of hypoalbuminaemia in the presence of salt and water overload (e.g. hepatic failure with ascites). Albumin has putative advantages that include limiting free radical-mediated damage but the importance of a normal serum albumin level remains uncertain.[9–11]

Human-derived colloid has a number of disadvantages. It is an expensive product and concerns have been raised about transmission of infectious agents – such as new-variant Creutzfeldt–Jakob disease (nvCJD) associated with bovine spongiform encephalopathy (BSE) – that are not removed by currently available techniques. Concerns have also been raised by the conclusions of a highly controversial meta-analysis suggesting that the use of human albumin solution may be associated with increased mortality in the critically ill.[11–13] These conclusions were probably unjustified for most collectives except for traumatic brain injury,[14] but there is currently no evidence that the use of human albumin has any advantages over less expensive semisynthetic alternatives[15,16] or indeed crystalloids. However, the latter still applies to all colloids.[14,17,18] The volume effect of 5% human albumin is approximately

90% when used to maintain blood volume during acute blood loss.[16]

GELATINS

Gelatins are prepared by hydrolysis of bovine collagen.[19] The commonly available preparations are succinylated gelatin (Gelofusine) and urea-linked gelatin–polygeline (Haemaccel).[2,3] The significant calcium content of Haemaccel makes it incompatible with citrated blood if infused through a giving set that has been previously used for this product; however, this does not apply to SAGM (saline–adenine–glucose–mannitol) blood. Gelatins are relatively inexpensive and stable, with long shelf lives. The gelatins' plasma-volume-expanding effect lasts only about 90–120 minutes.[5] They are mainly eliminated by renal excretion.

Incidences of reactions to gelatins are acceptable (<0.5%) and range from mild skin rash and pyrexia to life-threatening anaphylaxis. The gelatins appear to have the least impact on haemostasis and it is not clear whether they have any impact over and above simple haemodilution of clotting factors. A theoretical specific safety issue has arisen with bovine-derived gelatin products since the advent of sporadic cases of nvCJD associated with exposure to tissue infected with BSE. The gelatin used in the commercially available products in the UK, for example, is sourced from the US (which is regarded as BSE-free) or from certified BSE-free herds in France. The UK Spongiform Encephalopathy Advisory Committee concluded that gelatin was safe to use in this context.

The intravascular volume effect of older gelatin preparations appears to be inferior to that of human albumin or hydroxyethylstarch.[20] Reliable data on the newer generation are rare.

DEXTRANS

Dextrans are polysaccharides biosynthesised commercially from sucrose by the bacterium *Leuconostoc mesenteroides* using the enzyme dextran sucrase.[2,3] This produces a high-molecular-weight dextran that is then cleaved by acid hydrolysis and separated by repeated ethanol fractionation to produce a final product with a relatively narrow molecular weight range. The products are described by their MW – Dextran 40 and Dextran 70 having MWs of 40 000 and 70 000 Da respectively.

Dextran preparations are stable at room temperature and have long shelf lives. Dextran 70 is used as a plasma substitute for the treatment of hypovolaemia and has an intravascular volume-expanding effect that lasts at least 6 hours. Dextran 40 is used for its effects on microcirculatory flow and blood coagulation in some types of surgery (e.g. vascular, neuro and plastic surgery). The beneficial effects on outcome when Dextran 40 is used as an 'anti-sludging agent' remain controversial. Dextran 40 should not be used as a plasma substitute for the treatment of hypovolaemia as, although it produces an immediate plasma volume expansion as a result of its low molecular weight, it may obstruct renal tubules and produce renal failure.

Dextrans can precipitate true anaphylactic reactions, as anti-dextran antibodies may be present due to synthesis of dextrans by lactobacilli that occur naturally as gut commensals. Dextran infusion, particularly of the high-molecular-weight products, can also precipitate anaphylactoid reactions. The risk of true anaphylactic reactions can be decreased about 10-fold by pretreatment with monovalent hapten–dextran. The dextrans are also associated with significant haemostatic derangements. These include:

- haemodilution of clotting factors
- reduction in factor VIII activity
- increase in plasminogen activation
- increase in fibrinolysis
- reduction in clot strength
- impairment of platelet function.

Red cell aggregation is also reduced with the lower-molecular-weight dextrans. In patients whose haemostatic function is normal prior to infusion, a maximum dose of 1.5 g/kg is often recommended to avoid risk of bleeding complications. The anticoagulant effects of dextrans can be utilised perioperatively as a prophylaxis against thromboembolism.[2,3]

Due to the relevant side-effect profile and the requirement to pretreat with the hapten, dextrans are, in 2012, of minor relevance in Europe.

HYDROXYETHYL STARCHES

Hydroxyethyl starches (HES) are produced by hydroxyethyl substitution of amylopectin, a D-glucose polymer obtained from potato or waxy maize.[2,3] The pattern of hydroxyethyl substitution on glucose moieties influences the susceptibility to hydrolysis by non-specific amylases in the blood. A high C2 to C6 substitution ratio and a high overall degree of substitution (the proportion of glucose moieties that have been substituted) both protect against enzymatic breakdown and prolong the effective activity of HES. The different products are commonly described by their weight-averaged molecular weight (MWw: the number of molecules at each weight times the particle weight divided by the total weight of all the molecules) and their degree of substitution,[1–5] distinguishing hetastarches (0.6–0.7), pentastarches (≈0.5) and tetrastarches (≈0.4). Starch usage varies between countries.

There is a move towards the use of the non-saline-based starch as there is an association between the administration of high volumes of normal saline and a hyperchloraemic metabolic acidosis; the clinical significance of this phenomenon remains controversial.[21–27] Colloids presented in balanced electrolyte solutions are becoming available outside the USA. In Europe, the trend over the past 5 years has been towards the use of

lower-molecular-weight (130 kDa) tetrastarches presented in saline and more recently in balanced electrolyte solutions.[21] Starch preparations are stable at room temperature and have long shelf lives. The duration of intravascular retention is proportional to molecular weight[3,4,28,29] but is >6 hours even for the 130 kDa tetrastarches.

The initial volume effect of isooncotic HES preparations (6%) when infused to substitute actual intravascular deficits is close to 100%, irrespective of the generation.[28–30] HES products are associated with an acceptable incidence of adverse events including anaphylactoid reactions. Tissue deposition may result in intractable itching if large volumes of HES are infused over several days.[31] Whether the administration of large volumes of HES may cause some renal dysfunction or affect mortality in septic patients remains controversial.[32] The VISEP trial suggested hyperoncotic preparations of older generations in high dosage should be avoided in haemodynamically stable septic patients.[33] The 6S study, which found a significantly increased 90-day mortality after HES use, included 800 septic patients only *after* initial stabilisation,[34] as did the CHEST study, which found no difference in mortality and an unaltered renal state (RIFLE) after HES in 7000 ICU patients despite an increase in the use of renal replacement therapy.[35] Overall, no data currently prohibit the use of HES for use as a preload in the ICU patient. The perioperative use of modern HES preparations is currently not seriously questioned by available data, but neither safety nor efficacy has been demonstrated in large RCTs with long-term follow-up.[36]

HES products can cause a coagulopathy.[37] In particular, factor VIII (FVIII) levels are reduced and platelet function is impaired, causing a von Willebrand-like syndrome. These effects are greater with high-molecular-weight HES molecules infused at larger volumes and less in the reformulated balanced electrolyte alternative.[21] It is likely that in new-generation HES products some of the side-effects are attenuated.[38] However, their safety still needs to be proven.[33–36]

THE ROLE OF HYPERTONIC SOLUTIONS

In recent years hypertonic (600–1800 mosmol) crystalloid and colloid solutions have been introduced for certain clinical indications.[39–43] The theoretical advantage is that a small volume of administered fluid will provide a significant plasma volume expansion. The high osmolarity should draw tissue fluid into the intravascular space and thus should minimise tissue oedema for a given plasma volume increment. Colloids presented in a hypertonic saline carrier have been shown to achieve adequate resuscitation in a number of clinical settings. However, whether in fact a smaller volume of hypertonic solution really leads to a similar plasma volume expansion, in comparison to solutions with isotonicity, has never reliably been shown by direct blood volume assessment. From a physiological standpoint the idea that hypertonic crystalloid will drag water from the interstitial compartment may be optimistic, as electrolytes and other small osmolytes are not retained by the intact vascular barrier, in clear contrast to the blood–brain barrier. These solutions might result in reduced cerebral oedema in those patients at risk of this complication and these solutions may have a place in treating refractory cerebral oedema.[41–43] Outside the perioperative arena they are finding use in the management of burns patients and in prehospital resuscitation of trauma victim, being limited at present to single-dose administrations.

BLOOD SUBSTITUTES – PERFLUOROCARBON AND HAEMOGLOBIN THERAPEUTICS

In future, the use of artificial or semisynthetic oxygen-carrying solutions might become increasingly common.[44] A number of products have been and are currently under evaluation: perfluorocarbon, modified human haemoglobin (Hb), modified bovine Hb and recombinant Hb solutions. These products not only function as oxygen carriers but also are capable of sustained plasma volume expansion. Unlike Hb present in intact red cells, they often have a linear O_2-Hb dissociation profile and the effects on O_2 uptake in the lungs and release in the tissues are not yet clearly defined. Additionally, they may have specific pharmacological effects like nitric oxide scavenging, resulting in vasoconstriction. Nevertheless, a real artificial alternative to red cells as an oxygen carrier applicable in clinical routine will not be available in the near future.

PLASMA DERIVATIVES

FRESH FROZEN PLASMA

Fresh frozen plasma (FFP) contains normal plasma levels of all the clotting factors, albumin and immunoglobulin. A unit is typically 200–250 mL and has a FVIII level of at least 0.7 IU/mL (i.e. 70% of normal levels) and about 0.5 g of fibrinogen. It is kept at a temperature of −18°C or less in order to preserve coagulant levels. FFP is used for the replacement of multiple clotting factor deficiencies (e.g. liver disease, coumarin anticoagulant overdose and coagulopathy associated with massive blood transfusion).[45–47] An initial dose of at least 15 mL/kg (four packs for a 70-kg adult) is considered to be appropriate. Physiologically, in a normovolaemic patient, it might be better to correct any clotting factor deficit using a concentrate and then maintain the appropriate level using FFP instead of colloids in the face of ongoing bleeding or other volume deficit. This might decrease the risk of intravascular hypervolaemia, but currently there are no data to support using FFP in this way. FFP should not be used as a plasma volume expander, solely for the treatment of hypovolaemia.

CRYOPRECIPITATE

Cryoprecipitate is prepared by freeze-thaw of FFP, collection of the precipitate and then its resuspension in human plasma. It is a concentrate of FVIII, von Willebrand factor and fibrinogen and contains about 50% of the coagulant factor activity of the original unit (e.g. fibrinogen 250 mg, FVIII 100 IU). Cryoprecipitate is stored at –18°C and remains stable for up to a year.[45] It is indicated in the treatment of coagulation defects, including massive haemorrhage and DIC, if there is microvascular bleeding associated with a fibrinogen level <0.5 g/L. Also, it is, in principle, an alternative to the preferable FVIII or von Willebrand factor concentrates in the treatment of inherited deficiencies of those proteins.[46,47]

FACTOR VIII

Recombinant factor VIII is available but concentrates are also still prepared from pools of donor plasma and heat or chemically treated to inactivate HIV-1. It has a shelf life of 2–3 years. Chromatographic concentration results in high-purity FVIII, and the relative merits of high- and intermediate-purity products are being investigated.

Indications are the treatment of haemophilia A.[48] The dosage should carefully follow the recommendations of the respective manufacturers, targeting at plasma activities between 30 and 100%, depending on the clinical situation. Preferably, the strategy should be planned together with a specialist and will usually lead to a bolus of 25–50 U/kg, which can be repeated, for example, 12-hourly.

FACTOR IX COMPLEX

Factor IX complex (prothrombin complex concentrate, also called ‘PPSB’) contains the vitamin-K-dependent factors II, VII, IX and X in varying amounts, and is prepared from pools of plasma.[45] It is a freeze-dried preparation reconstituted with water immediately before use. Factor IX complex is mainly used to correct bleeding disorders due to an overdose of the vitamin K antagonistic coumarin anticoagulants in patients who cannot tolerate large volumes of FFP.[45] Purified factor IX concentrates are now available and appear preferable in haemophilia B.

OTHER PLASMA CONCENTRATES

Activated factor VII concentrate can be used in the very rare deficiency of FVII, but also, in principle, in patients with inhibitors to factor VIII or IX, as it bypasses the requirement for these factors.[45] The use of the specific factor concentrations is preferable. The use of activated factor VII in the management of severe life-threatening haemorrhage remains controversial.[49] Other concentrates, such as antithrombin III, C1 esterase inhibitor and proteins C and S, have been used experimentally with varying success for the treatment of DIC and septic shock. Recombinant activated protein C preparation (Drocegogin alfa, Xigris™, Eli Lilly, Indianapolis, USA) for the treatment of septic shock[50] (see Ch. 15) was withdrawn in 2011 owing to its unclear benefit and an increased risk of bleeding.

IMMUNOGLOBULINS (GAMMA GLOBULINS)

Human immunoglobulin preparations are pooled from plasma from normal blood donors. It contains antibodies to hepatitis A, measles, mumps, varicella, polio and prevalent bacteria, reflecting the plasma of the donors.[45] Immunoglobulins are indicated in the prevention or treatment of patients with hypogammaglobulinaemia, and may have a role in the treatment of autoimmune diseases, such as thrombocytopenic purpura and myasthenia gravis. Specific immunoglobulins are available for a range of infectious agents including tetanus, hepatitis B, rubella, measles, rabies and varicella zoster. They are made from donor plasma known to contain high levels of the specific IgG antibodies and are used for prophylaxis and treatment in patients who have not been actively immunised. Rhesus-D immunoglobulin is prepared from plasma containing high levels of anti Rh-D antibodies and it prevents sensitisation of Rh-negative mothers to Rh-D positive cells that may enter their circulation. The principal use of Rh-D immunoglobulin is in the prevention of haemolytic disease of the newborn.[51]

Therapeutic plasma exchange and intravenous immunoglobulin therapy

Ian Kerridge, David Collins and James P Isbister

Blood letting to remove 'evil humours' has been practiced for over 2000 years. But although the restoration of 'balance' and the removal of 'noxious' agents from the blood remains the rationale for apheresis, contemporary practice is now based upon an extensive scientific understanding of the pathophysiology of the diseases treated by plasma exchange.[1] Exchange transfusions revolutionised the management of haemolytic disease in the newborn, and paved the way for therapeutic plasmapheresis and plasma exchange – the removal of plasma, with replacement by albumin–electrolyte solutions or fresh frozen plasma. Initially used in the management of hyperviscosity associated with malignant paraproteinaemia, it is now also used in the treatment of more than 100 autoimmune disorders but is expensive, not risk-free and debate continues on its therapeutic role in many diseases.

Intravenous immunoglobulin (IVIG) – once used purely as replacement therapy for patients with primary humoral immune deficiency – has also become increasingly used as an immunomodulatory agent. Its relevance in this chapter is that it is now being used in many disorders in which plasma exchange is effective, but the convenience and safety of IVIG therapy is preferred as an alternative. The underlying principles in managing autoimmune diseases with IVIG are similar to those of therapeutic plasma exchange. The immunomodulatory mechanism of action of IVIG remains controversial and it is likely, as with plasma exchange, that there is more than one mechanism in play. Therapeutic efficacy of IVIG has been established in controlled trials for a range of diseases including idiopathic thrombocytopenic purpura, Kawasaki disease, Guillain–Barré syndrome, dermatomyositis and others. There is compelling evidence that IVIG can modulate immune reactions of T cells, B cells and macrophages, thus interfering with antibody production and degradation, but also modulating the complement cascade and cytokine networks.

RATIONALE FOR PLASMA EXCHANGE

Theoretically, plasma exchange should be effective to treat any disorder in which there is a pathogenic circulating factor responsible for disease. However, it is increasingly clear that this premise is too simplistic as many other mechanisms have been found to contribute to its beneficial effects (**Box 97.1**). Plasma exchange brings about numerous alterations in the plasma's *milieu interieur* – which may be clinically beneficial or detrimental.

PATHOPHYSIOLOGY OF AUTOIMMUNE DISEASE

Autoimmune disease originates from the breakdown of immunoregulation (i.e. immune tolerance), allowing the immune system to become autoaggressive. Autoimmune diseases with underlying humoral mechanisms result from either a circulating autoantibody against a self-antigen (alone or in combination with an environmental antigen), or circulating immune complexes (which may be deposited in the microcirculation of various organs, resulting in end-organ damage). Cellular and tissue damage are effected by the autoantibody or immune complexes activating the cellular and humoral components of the inflammatory response. The circulating proteolytic systems involved include the complement, coagulation, fibrinolytic and kinin systems. On the cellular side, neutrophils and macrophages are involved, with eosinophils and basophils also playing a part.

The varied clinical manifestations of autoimmune disorders relate more to the cell, tissue or organ involved, rather than the pathophysiological process. However, basic pathophysiological mechanisms by which autoimmune diseases occur need to be understood in order to standardise treatment. Although some cells of the host defence system, in particular the macrophages and lymphocytes, may have special differentiation appropriate to individual organs, their basic functional processes are not all that dissimilar between different organs.

In general, autoimmune disease can be an acute, self-limiting ('one-hit') disorder, intermittent or a chronic perpetuating disorder. Acute autoimmune disease may have an identifiable trigger, such as an infection, followed by a 10-day to 3-week gap until the pathogenic humoral or cellular factors appear in the circulating blood. At this point, end-organ damage commences, and clinical features of the disease appear.

Box 97.1 Rationale for plasma exchange

Removal of circulating toxic factor antibodies
- Monoclonal antobodies
- Autoantibodies
- Alloantibodies

Immune complexes
Chemical drugs
Depletion of mediators of inflammation
Replacement of deficient plasma factor(s)
Potentiation of drug action
Enhanced reticuloendothelial function
Altered immunoregulation
Potentiating effect of plasma exchange on other modes of therapy (e.g. glucocorticoids)

The course of the disease will be determined by several factors:

- biological function and importance of the system involved
- extent of damage
- replaceability or otherwise of the cells under attack
- time course of the damaging insult.

The extent of damage, in turn, is a product of the:

- characteristics of the antibodies or lymphocytes involved (e.g. antibody affinity, complement fixing capabilities and titre)
- function of other components of the host defence system (e.g. neutrophils, platelets, proteolytic systems and reticuloendothelial system)
- presence of other aggravating factors (e.g. infection, hormonal responses and circulatory responses).

The kinetics of the end-cell involved in the immunological damage is relevant in determining the final outcome of the disease. Ultimate recovery of organ function after 'burn-out' of a self-limiting autoimmune disease, or control of a chronic autoimmune disease, is determined by the ability of the cell to replace and restore function to normal.

Cells are broadly divided into three kinetic characteristics:

- *Continuous replicators:* these cells are continuously replaced in the normal state, are readily replaced when damaged, and if the immunological insult is removed or controlled then full replacement of the end-cells occurs. Typically seen with the haemopoietic system, the cells lining the gut and skin cells.
- *Discontinuous replicators:* these are cells that are not being constantly replaced in the normal state, but when damaged, cell division is initiated and replacement occurs. This is seen with hepatocytes, renal tubular cells and the neuronal Schwann cell.
- *Non-replicating cells:* these cells when damaged are irreplaceably destroyed with permanent loss of function. This is seen with neuronal cells, muscle cells and renal glomeruli.

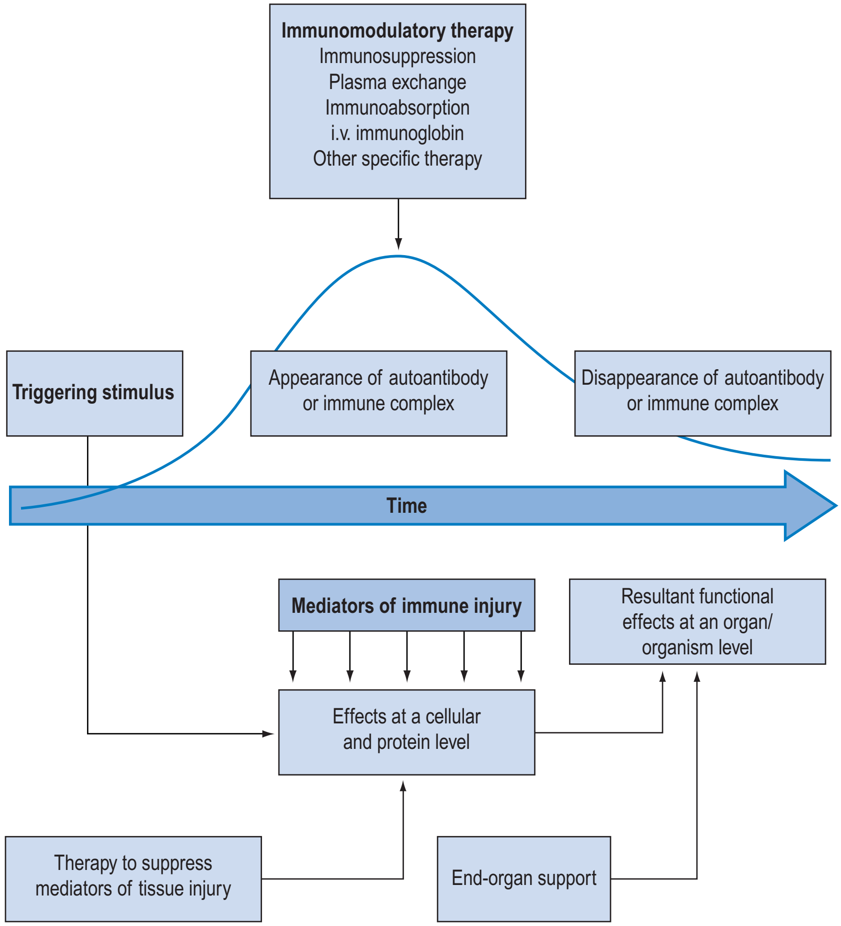
The clinical features and final outcome of any autoimmune disease are determined by many different factors, including the ability of the end-organ to repair following removal or control of the immunological insult. In many self-limiting autoimmune diseases, if the end-cell is a continuous or intermittent replicator then full recovery can be expected, after recovery from the acute phase of the illness. Examples are acute tubular necrosis, acute demyelination, acute hepatic failure and some forms of marrow aplasia. In contrast, in disorders involving non-replicating cells such as acute glomerulonephritis, therapy must be aimed at removing the immunological insult or dampening its damaging affects as soon as possible so as to minimise irreparable damage to the end-cells and thus long-term organ function. Immunological mediators may also produce disease without direct destruction of end-cells. This occurs when autoantibodies develop against cell receptors with blocking or destruction of the receptor, as may typically be seen in myasthenia gravis and thyrotoxicosis.

Therapy in acute and chronic autoimmune disease aims to minimise irreparable end-organ damage and support patients during the acute illness. This therapy may include:

- non-specific therapy to suppress the effector mechanisms (e.g. corticosteroids, antiplatelet therapy, non-steroidal anti-inflammatory drugs, anticoagulation and depletion of humoral effector mechanisms by plasma exchange or defibrination)
- therapy to reduce the circulating levels of a humoral factor, which is achieved with plasma exchange or immunoabsorption technique
- specific or broad-spectrum immunosuppressive agents to suppress or block the immune response (e.g. corticosteroids, cytotoxic agents, anti-lymphocyte globulin, high-dose intravenous gamma-globulin therapy)
- therapy directed at altering reticuloendothelial function, which may then have effects on autoantibody and immune complex clearance, or clearance of circulating damaged cells
- intravenous immunoglobulin (IVIG) immunomodulatory therapy.

As most disorders are multifactorial, it is unlikely that a single form of therapy will be successful, so a multipronged approach to therapy needs to be based upon analysis of the underlying pathophysiology. The stage of the disease is also important (**Fig. 97.1**). Clearly, plasma exchange will have a different response when autoantibody production is rising rapidly, compared with a stage when autoantibody has ceased production. Also, immunoregulation is a complex process and therapies may interfere at different points in the immune mechanisms.

Figure 97.1 The therapy of 'one-hit' autoimmune disease.



In some circumstances, specific and directed therapy may attack the most relevant link in the pathophysiological chain, but overall multiple approaches to therapy may be required. In general, plasma exchange is a temporising procedure and concomitant immunosuppressive therapy is required to maintain control. Plasma exchange should generally be regarded as a first step in immunomodulatory therapy, and restricted to acute or fulminant situations in which autoantibodies or immune complexes are responsible for life-threatening or end-organ-damaging complications. If the humoral factor is only transient (' a one antigen hit' disorder), then no follow-up immunosuppression is required (e.g. acute post-infectious polyneuritis). Increasingly, monoclonal antibody therapy with rituximab (an anti-CD20 antibody) is finding a role in the longer-term management of autoimmune diseases.[2,3]

The recognition of the immunomodulatory effects of IVIG has resulted in an exponential increase in its use in immune and inflammatory disorders – with availability being one of the main drivers of the supply of human-derived plasma products. Indeed, in most of the immune and inflammatory disorders in which plasma exchange has been used, IVIG has been used – often with equal efficacy.[4]

TECHNICAL CONSIDERATIONS

Plasma exchange can be by filtration, centrifugation, or a combination of both, depending on the equipment available. There are a number of apheresis machines on the market. Filtration plasma exchange is found on a number of dialysis machines and uses a semipermeable membrane with small holes or pores up to 0.2 μm in diameter; this is approximately 30 times the diameter of the pores found in conventional high-flux haemofilter membranes.[5] Blood is pumped into this chamber and the plasma passes through the membrane; this membrane will allow the passage of substances up to 3×10^6 Da, separating substances such as immunoglobulins, immune complexes and complement factors from the cellular part of the blood.[5] The plasma is then diverted to a waste bag and the remaining cellular product mixed with replacement fluid and returned to the patient.

Apheresis machines using centrifugation use continuous or intermittent blood flow. The continuous flow

machines pump blood through a band centrifuge; applied G-force separates out the blood according to its molecular weight, and the particular product (in this case the plasma) is removed and pumped to the waste bag, with the remaining cellular material being mixed with the replacement fluid and returned to the patient.[6] Intermittent centrifugation uses a Latham bowl, which fills with blood, is centrifuged, the plasma separated to a waste bag and the cellular products returned to the patient with replacement fluid. This procedure can be carried out through one vein; however, it is a longer procedure than the continuous-flow machines.[6]

The extracorporeal blood is anywhere between 150 and 250 mL depending on the machine being used. There is cooling in the extracorporeal circuit, and the replacement fluids will be cool so consideration should be given to maintain body temperature, with a blood warmer and warming blankets.[7]

Good venous access is needed for continuous blood flow, at between 30 and 100 mL/min depending on the replacement fluid and the patient's condition. As the patient may require multiple procedures, consideration must be given for appropriate venous access such as a vas-cath.

Most apheresis machines use regional anticoagulation, with citrate added as blood enters the apheresis circuit. Pooled plasma also contains citrate so, if used, the amount of citrate returned to the patient is further increased. It should be noted, however, that citrate toxicity can also occur when albumin is used, as this is a calcium-free and calcium avid-binding solution.[7] Although citrate is plasma-bound and relatively short-acting there will still be some returned to the patient where it is metabolised. Patients with abnormal liver functions will take longer to metabolise the citrate and therefore have an increased risk of citrate toxicity. Citrate toxicity produces hypocalcaemia with symptoms including acral or oral paraesthesia, light-headedness, tetany, nausea, vomiting and cardiac arrhythmias.[8] The drop in calcium levels occurs within the first 15 minutes of the procedure,[7] therefore attention should be paid to the patient's serum calcium and if required supplementation commenced prior to the start of the procedure. Calcium gluconate 10% at a dose of 2 mL per 250 mL of replacement fluid has been recommended; this can be added to the albumin or run as a concurrent infusion.[9,10] Other electrolytes can also become depleted, and should therefore be monitored and replaced as required.[7] Magnesium also binds to citrate and there can be up to a 60% fall in the blood levels of patients; however, concurrent supplementation is not recommended as routine.[7]

Occasionally the apheresis circuit is secondary to heart bypass, extracorporeal membrane oxygenation (ECMO) or renal dialysis. The literature is limited but it has been reported as safe.[7] For ECMO and heart bypass, the apheresis practitioner must work closely with the medical staff and perfusionist to ensure the patient's safety. Where renal dialysis is involved there should be negotiation as to the timing of the procedures. In most cases it is preferable for plasma exchange to be performed prior to dialysis so that any extra fluid given during the procedure can be removed by dialysis.

INDICATIONS (Box 97.2)

Plasma exchange is most beneficial for immunoproliferative and autoimmune diseases. In some conditions with unclear pathophysiology, the beneficial effects of plasma exchange may be due to infusion of a deficient component in the replacement plasma, rather than removal of a circulating factor.

The American Society for Apheresis (ASFA) has published comprehensive 'Guidelines on the Use of Therapeutic Apheresis in Clinical Practice: Evidence-based

Box 97.2 Acute diseases in which plasma exchange may be beneficial*

Immunoproliferative diseases with monoclonal immunoglobulins
Hyperviscosity syndrome
Cryoglobulinaemia
Renal failure in multiple myeloma

Autoimmune diseases due to autoantibodies or immune complexes
Goodpasture syndrome
Myasthenia gravis
Guillain–Barré syndrome
Chronic inflammatory demyelinating polyneuropathy (CIDP)
Stiff-man syndrome
Systemic lupus erythematosus
Fulminant antiphospholipid syndrome
Thrombotic thrombocytopenic purpura
Haemolytic uraemic syndrome
Rapidly progressive glomerulonephritis
Coagulation inhibitors
Autoimmune haemolytic anaemia
Pemphigus
Paraneoplastic syndromes

Conditions in which replacement of plasma may be beneficial +/− removal of toxins
Disseminated intravascular coagulation
Multi-organ dysfunction syndrome
Overwhelming sepsis syndromes (e.g. meningococcaemia)

Conditions in which the mechanisms are unknown
Reye's syndrome

Removal of protein-bound or large-molecular-weight toxins
Paraquat poisoning
Envenomation

*This is an incomplete list and includes only disorders that are relatively common or in which plasma exchange has a definitive role to play.

approach from the Apheresis Applications Committee of the American Society for Apheresis'.[11] The ASFA guidelines describe four categories of disorder on the basis of a review of the available literature on the efficacy of TPE. These are as follows:

- *Category I*: 'Disorder for which apheresis is accepted as first-line therapy, either as a standalone treatment or in conjunction with other modes of treatment.'
- *Category II*: 'Disorders for which apheresis is accepted as second-line therapy, either as a standalone treatment or in conjunction with other modes of treatment.'
- *Category III*: 'Optimum role of apheresis therapy is not established. Decision-making should be individualised.'
- *Category IV*: 'Disorders in which published evidence demonstrates or suggests apheresis to be ineffective or harmful. Internal Review Board approval is desirable if apheresis treatment is undertaken in these circumstances.'

Category I disorders include: myasthenia gravis, Guillain–Barré syndrome, Goodpasture syndrome (anti-GBM antibody disease), cryoglobulinaemia, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), sickle cell disease (acute stroke) and Wegener's granulomatosis.

Category II disorders include: multiple sclerosis, neuromyelitis optica, acute disseminated encephalomyelitis, ABO-incompatible solid organ transplantation and catastrophic antiphospholipid syndrome.

Category III disorders include: aplastic anaemia, autoimmune haemolytic anaemia, paraneoplastic neurologic syndromes, erythrocytosis, acute liver failure, immune complex rapidly progressive glomerulonephritis and sepsis and multi-organ failure.

Category IV disorders include: dermatomyositis or polymyositis, ITP, rheumatoid arthritis, chronic progressive multiple sclerosis, scleroderma, amyloidosis and inflammatory bowel disease.

MONOCLONAL ANTIBODIES ASSOCIATED WITH IMMUNOPROLIFERATIVE DISEASES

Monoclonal immunoglobulins are a classical feature of multiple myeloma and Waldenström's macroglobulinaemia, but may also be associated with other lymphoproliferative disorders. These monoclonal proteins may be associated with numerous clinical effects, many of which may be reversed by plasma exchange:

- *Hyperviscosity syndrome:* characteristic clinical features of hyperviscosity in association with monoclonal proteins include visual disturbance, neurological dysfunction and hypervolaemia. All are rapidly relieved by plasma exchange.[12]
- *Haemostatic disturbances:* monoclonal proteins may impair haemostasis by adversely affecting platelet function or by inhibitory effects on coagulation factors. Plasma exchange is usually effective in controlling haemorrhage and may also be helpful in preparing patients for surgery.
- *Renal failure*: the development of renal failure in the course of multiple myeloma is generally regarded as a sign of poor prognosis. The renal failure is often multifactorial in origin, but some of these factors may be reversible by plasma exchange. Patients presenting acutely with hyperviscosity, dehydration and hypercalcaemia may show recovery of renal function following adequate hydration, alkaline diuresis and plasma exchange.

IMMUNOLOGICAL DISEASES

DISEASES MEDIATED BY SPECIFIC AUTOANTIBODIES

Goodpasture syndrome

In Goodpasture syndrome circulating antiglomerular basement membrane antibodies can often be demonstrated. The disease classically has a fulminant presentation with rapidly progressive renal failure and life-threatening pulmonary haemorrhage. Early diagnosis and intensive plasma exchange may be necessary to preserve renal function and control pulmonary haemorrhage. Patients who are already in anuric renal failure rarely show improvement in renal function.[13]

Myasthenia gravis

Removal of the acetylcholine receptor autoantibody is often associated with clinical improvement, but the beneficial effects of plasma exchange are usually transient, so the procedure should be used in conjunction with other forms of therapy (see Ch. 57, Myasthenia gravis). The major role of plasma exchange is in myasthenic crisis, in patients whose condition is resistant to other forms of therapy, and prior to surgery. Therapy can be monitored by acetylcholine receptor autoantibody assays and respiratory function tests. During the procedure patients may transiently deteriorate, owing to a combination of the physical exertion and removal of medication from the circulation. Adequate ventilatory support should be available. IVIG may also be use in myasthenia gravis.[14–16]

Stiff-man syndrome

Stiff-man syndrome is a rare neurological disorder characterised by involuntary axial and proximal limb rigidity and continuous motor unit activity on electromyography. Autoantibodies to glutamic acid decarboxylase are usually demonstrable and plasma exchange is often successful in those in whom autoantibody can be demonstrated, but if negative they are less likely to respond.[17,18]

Autoimmune haematological disorders

Haemostatic failure due to autoantibodies directed against coagulation factors may present a major

management problem. Antibodies directed against factor VIII are the commonest, occurring spontaneously or in association with replacement therapy in haemophiliacs. First-line therapy in patients with coagulation factor inhibitors usually requires activated factor VII therapy with recombinant VIIa or appropriate prothrombin concentrates.[19]

IMMUNE COMPLEX DISEASE

Rapidly progressive glomerulonephritis

Immune-complex-induced rapidly progressive glomerulonephritis may occur by itself or be associated with several systemic disorders (e.g. systemic lupus erythematosus, polyarteritis nodosa, IgA nephropathy, post-streptococcal infection and Wagener's granulomatosis).[20–22] Plasma exchange may result in improvement in renal function even in patients who present with anuria. The decomplementing and defibrinating effects of plasma exchange may be partly responsible for clinical improvement. The therapeutic role of plasma exchange in rapidly progressive glomerulonephritis is difficult to assess, but most experienced physicians feel that the procedure leads to a more rapid and complete recovery of renal function in fulminant, rapidly deteriorating cases. However, the ultimate prognosis of the disease depends on adequate immunosuppression to inhibit immune complex formation, or spontaneous disappearance of the inciting antigen.

Systemic lupus erythematosus (SLE)

In acute life-threatening or organ-damaging relapses of SLE, plasma exchange should be considered if there is rapid deterioration in renal function, cerebritis, or acute fulminant lupus pneumonitis.[23]

Cryoglobulinaemia

The various forms of cryoglobulinaemia may be associated with vasculitis or hyperviscosity. If there is an acute fulminant presentation with cutaneous vasculitis, renal failure, and neurological impairment then plasma exchange should be considered an urgent definitive form of therapy.

OTHER IMMUNE-MEDIATED DISEASES

Renal transplant rejection

Humoral mechanisms appear to play a part in hyperacute renal allograft rejection. Plasma exchange +/− IVIG may be useful in tiding patients over episodes of acute graft rejection. However, results of clinical trials have been conflicting.[24,25] General opinion is that plasma exchange helps in a limited number of patients who cannot be currently preselected by any clinical or laboratory criteria.

Thrombotic microangiopathies

The thrombotic microangiopathies describe a number of syndromes characterised by disseminated microvascular thrombosis, thrombocytopenia and (often) anaemia. They include thrombotic thrombocytopenic purpura (TTP), haemolytic uraemic syndrome (HUS), disseminated intravascular coagulation (DIC), catastrophic antiphospholipid syndrome (CAPS) and paediatric thrombocytopenia-associated multiorgan failure (TAMOF).

Thrombotic thrombocytopenic purpura

TTP is a potentially fulminant and life-threatening disorder characterised by platelet microthrombi in small vessels, resulting in microangiopathy. The clinical syndrome is manifest by the pentad of thrombocytopenia, microangiopathic haemolytic anaemia, fever, renal dysfunction and neurological abnormalities. Abdominal symptoms, hepatic dysfunction and pulmonary abnormalities may also occur. With the appropriate clinical features, thrombocytopenia and a microangiopathic blood film, diagnosis is established.

TTP has been linked to a severe deficiency in ADAMTS13 with metalloprotease activity with its target cleavage sequence in von Willebrand factor (VWF). The presence of an autoantibody inhibitor to this vWF-reducing metalloproteinase has been documented in patients with both acute TTP and those with chronic relapsing forms. In normal plasma vWF undergoes proteolysis by a specific protease and deficiency of this cleaving protease reduces or abolishes the plasma clearance of ultralarge vWF multimers, resulting in intravascular aggregation of platelets particularly at sites of intravascular shear stress. The inhibitor to the metalloproteinase has been demonstrated to be an IgG autoantibody.

There is a primary idiopathic form of the disease that usually has an acute presentation and probably has an underlying autoimmune mechanism. This form may be associated with a variety of prodromal infections (viral or bacterial). Bacterial cytotoxins, produced by *Shigella dysenteriae* 1 and certain *E. coli* serotypes, have been related to TTP and HUS, probably by initiating damage to vascular endothelial cells possibly via cytokine mechanisms. TTP may be associated with various drugs (cytotoxic agents), toxins and bites. CMV, HIV and herpes viruses have also been implicated. Chemotherapy-associated thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome is being increasingly recognised and may be associated with a range of cytotoxic medications. Severe microangiopathy resembling TTP has also been reported as a complication of acute graft-versus-host disease in patients receiving ciclosporin prophylaxis following allogeneic BMT.

TTP used to be fatal disease in 90% of patients, but dramatic improvement in its outcome has occurred over the past two decades. Plasma exchange has become the cornerstone of the treatment with cryoprecipitate-poor plasma (depleted in VWF).[26,27] It is now possible to achieve remissions in the majority of patients and

cures are now common, although unfortunately relapse may occur. The clinical course at relapse is usually milder than the disease at presentation and less-aggressive therapy may be needed.

Haemolytic uraemic syndrome (HUS)

This syndrome has many similarities to TTP, but in contrast to cerebral TTP, renal involvement is the hallmark of microangiopathy and thrombocytopenia.[28] HUS is commonly categorised into 'typical' and 'atypical' HUS.

Typical HUS, the majority of cases, is commonly associated with infection and diarrhoea – most commonly caused by the Shiga-toxin producing *Escherichia coli* 0157:H7, which induces release of ultra-large vWF from the endothelium and inhibits ADAMS-13. Less often, HUS may present insidiously and the cause, which may include chemotherapy, radiotherapy or other medications, may be unclear. Therapeutic plasma exchange is generally not recommended for typical HUS associated with infection – which is often self-limiting and has a mortality of less than 5%. Although it is often tried in adult patients with HUS and in patients with typical HUS of more indeterminate cause – the results are often disappointing.

Atypical HUS is thought to result from genetic mutations in the complement pathway or from acquired autoantibodies against factor H, which result in uncontrolled activation of the alternative complement pathway and direct injury to the microvasculature. Plasma exchange is recommended for atypical HUS – which has a mortality rate of approximately 25%.

It is often difficult to distinguish atypical HUS from typical HUS and HUS from TTP, particularly in the acute setting – so plasma exchange is often initiated until the results of genetic studies and biomarkers can assist in clarifying the diagnosis.

Inflammatory demyelinating neuropathies and Guillain–Barré syndrome

This acute self-limiting disease in which an acute demyelinating neuropathy occurs (usually following a viral infection) commonly results in admission to the ICU (see Ch. 57, Guillain–Barré syndrome). The demyelination is due to post-infectious autoimmunity, with both cellular and humoral arms of the immune system attacking myelin. There is now wide experience in the use of plasma exchange and IVIG therapy in Guillain–Barré syndrome, with controlled trials substantiating its benefits of shortening of the illness, and complications. Therapy should be instituted early.[16,29] As Guillain–Barré syndrome also responds to high-dose IVIG, there is debate as to which should be the first line of therapy; as the therapies have comparable efficacy and safety, decisions are usually made on the basis of local logistics and economics.[30] In some cases the onset of recovery after therapy may be delayed, probably due to time for remyelination to occur. Some patients show rapid improvement after plasma exchange, suggesting the presence of neuronal blocking factors. Chronic inflammatory demyelinating peripheral neuropathy (CIPD) is related to the GBS and plasma exchange and/or IVIG have important roles in treatment, in many cases requiring long-term therapy.

COMPLICATIONS

Plasma exchange is a relatively safe procedure, with a case–fatality rate of 3–5 per 10 000 procedures – mainly as a consequence of cardiac arrest, cardiac failure and transfusion-associated acute lung injury (TRALI). Minor complications due to fluid shifts, electrolyte abnormalities and exposure to blood products are common and for these reasons close supervision by experienced physicians and apheresis operators with a sound understanding of the haemodynamic, biochemical, haematological and immunological effects of plasma exchange is of paramount importance.[31,32]

Assessment prior to commencing the procedure should include vascular access, haemodynamic stability, transfusion history, relevant co-morbidities and concomitant medications. Any medication that is highly plasma-bound or has a low volume of distribution is likely to be removed.[33,34] If there is any concern that a drug may be removed during the procedure then it should be withheld until completion, or the effects monitored during the procedure and additional doses given as required.[35] Where possible, ACE inhibitors and angiotensin receptor blockers should be stopped 24 hours prior to plasma exchange.[36] This is because these drugs will decrease the patient's ability to activate bradykinin, which in turn can lead to flushing, hypotension, and respiratory distress.[34]

Potential complications of plasma exchange include: fluid imbalance, reactions to replacement fluids, vasovagal reactions, pyrogenic reactions, hypothermia, embolism (air or microaggregates), hypocalcaemia, anaemia, thrombocytopenia, haemostatic disturbances, hepatitis, hypogammaglobulinaemia, and altered pharmacokinetics of drugs. Specific note should be made of the following effects.

CIRCULATORY EFFECTS

Any extracorporeal procedure is likely to lead to problems of circulatory instability. Intravascular volume changes, vasovagal reactions, medications and infusion fluids may alone, or in combination, be responsible for circulatory problems. Often the patient will be able to compensate but if there are pre-existing issues (e.g. altered blood volume, vascular disease, or renal failure) then close monitoring is essential. A strict fluid and electrolyte balance should be kept at all times, both during the plasma exchange and also as a daily tally.

PLASMA ONCOTIC PRESSURE (COP)

Most patients compensate for minor fluctuations in COP. Patients who have oedema or local factors predisposing to interstitial fluid accumulation (e.g. raised intracranial pressure, interstitial pulmonary oedema, deep venous thrombosis, and renal impairment) need close attention.

INFECTION

Many patients who are undergoing plasma exchange are already immunosuppressed, either due to their disease or secondary to drug therapy. In patients requiring recurrent and frequent plasma exchange, attempts should be made to maintain serum immunoglobulin levels. When fresh frozen plasma is not used as replacement fluid, the bacteriocidal and opsonic activities of blood are probably impaired, and it is probably advantageous to infuse at least two units of fresh frozen plasma at the conclusion of the procedure. At the completion of a course of plasma exchange, consideration may need to be given to a dose of intravenous gammaglobulin.

HAEMOSTASIS

Plasma exchange, particularly where albumin is used as the replacement fluid, causes perturbations in the haemostatic system, which may result in either bleeding or thrombosis. The significance of these alterations will depend largely on the volume and frequency of exchange, pre-existing defects in the system, anticoagulation, other risk factors for thrombosis, replacement fluids and invasive procedures.[31]

REACTIONS TO REPLACEMENT FLUIDS

The rapid infusion of any blood component may be associated with allergic or vasomotor reactions. Plasma exchange is a rather unique situation as blood or blood products and plasma substitutes are being infused at resuscitation rates into normovolaemic, normotensive patients.

Hypotension can occur at any point in the procedure and although plasma exchange will maintain the patient as normovolaemic, there is always the risk of reaction to the exchange fluid or fluid shifts within the patient. Fluid shifts will normally respond to slowing down or halting the procedure and giving a bolus of fluids until there is recovery of the blood pressure.[37] It is helpful to ensure adequate hydration of the patient prior to commencing the procedure as this will also help reduce the risk. It should be noted that many patients have a small drop in their systolic blood pressure within minutes of commencing the procedure. Patients with neurological disorders may also benefit from running the procedure in a positive fluid balance to help counteract a lack of peripheral venous resistance.

Reactions to plasma can be seen as the development of pruritis or urticaria and necessitate the administration of an antihistamine. If there is chest tightness, acute dyspnoea, or hypoxia and the patient is receiving plasma as the replacement fluid then consideration should be given to transfusion-related lung injury (TRALI) (caused by infusion of Class I or II HLA or anti-neutrophil antibodies from donor plasma which react with recipient leucocytes and cause leucoagglutination in pulmonary circulation) and appropriate treatment commenced.[9]

Where albumin is the replacement fluid on consecutive days, attention should be paid to coagulation parameters as there may be dilution of clotting factors. In patients with normal liver function, it would be expected that these would return to normal within a few days of ceasing plasma exchange; however, if the patient has had a recent haemorrhage or is pre or post surgery then the use of donor plasma may be justified.[7]

EFFECTS OF INTRAVASCULAR PROTEINS

If plasma protein fractions or albumin are being used for replacement fluids, not only will coagulation and complement components be depleted, but various transport and binding proteins in the circulation are significantly reduced. These may have significant effects on drug activity and elimination (e.g. antithrombin III levels may have effects on heparin activity). The effects of corticosteroids may be potentiated after plasma exchange owing to a reduction in binding proteins.

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin (IVIG) products were originally developed in the 1950s for the treatment of immunodeficiency states. Since then, the immunomodulatory properties of IVIG have led to much broader usage in autoimmune and inflammatory disorders – usually in much higher doses.[38] In many cases the use of IVIG is based upon very limited evidence and much of the IVIG used is prescribed for 'off-label' indications.[39] Consequent shortages of IVIG and concerns regarding the costs of IVIG have led governments worldwide to attempt to restrict its use to only those conditions in which it has an established or emerging role.

IVIG is a sterile fractionated blood product consisting of concentrated immunoglobulin derived from pooled human plasma from thousands of healthy blood donors. IVIG typically contains more than 95% unmodified IgG (which has intact Fc-dependent effector functions) and trace amounts of IgA and IgM, cytokines, soluble CD4, CD8 and HLA molecules. Because IVIG is derived from large numbers of donors this provides a rich diversity of antibody repertoires and specificities.

A range of IVIG products are available. Although all contain IgG molecules, they may differ in regards to

their pH, osmolality, excipient compounds (sucrose/sodium) and consequently in their adverse effects. In recent years IVIG preparations have been progressively improved – with the elimination of sugars and normalisation of salt content and pH – which has significantly reduced the incidence of adverse reactions.[40] At present there is a lack of good comparative data to suggest that one IVIG preparation is superior to another.

IVIG has multiple immunomodulatory and anti-inflammatory activities including: modulation of complement activation with inhibition of generation of membrane attack complex (C5b-9) and subsequent complement-mediated tissue damage, suppression of idiotype antibodies, neutralisation of 'super-antigens', saturation of Fc receptors on macrophages and suppression of various inflammatory mediators including cytokines (TNF-α, IL-1α, IL-6), chemokines, adhesion molecules and metalloproteinases.[42] Importantly, many of these effects extend beyond the half-life of IVIG (IVIG lasts 6–22 days in circulation), suggesting that the immunomodulatory effects of IVIG are not simply due to enhanced passive clearance of autoantibodies or interference with pathogenic autoantibodies.

INDICATIONS FOR IVIG (BOX 97.3)

IVIG has an established role in the treatment of primary immune deficiency and in acquired humoral immunodeficiency states due to haematological malignancies (particularly chronic lymphocytic leukaemia and multiple myeloma) and organ transplantation.[41] It also has an established role in many other conditions associated with autoimmune dysregulation as an immunomodulatory therapy including Guillain–Barré syndrome (GBS), idiopathic thrombocytopenic purpura, myasthenia gravis, chronic inflammatory demyelinating polyneuropathies (CIDP) and Kawasaki disease. IVIG is often as efficacious as plasmapheresis and so is often recommended as first-line therapy with therapeutic plasma exchange used for patients who are unresponsive to IVIG and immunosuppressive therapy (generally corticosteroids).[42,43] IVIG is considered as second- or third-line therapy in a number of other conditions in which standard therapies have been ineffective or are contraindicated and/or where the available evidence is inconclusive. Opinion remains divided as to whether IVIG has any role in sepsis. Despite a biological rationale for its use (based largely on preclinical work demonstrating enhanced bacterial clearance, inhibitory effects on mediators of inflammation and attenuated lymphocyte apoptosis) there is inconsistent evidence regarding its therapeutic efficacy.[44–46]

Box 97.3 Diseases in which IVIG has an established benefit

Acquired hypogammaglobulinaemia secondary to haematological malignancies
Chronic inflammatory demyelinating polyneuropathy
Guillain–Barré syndrome
Idiopathic (autoimmune) thrombocytopenia purpura (ITP) in adults
Inflammatory myopathies
Kawasaki disease
Lambert–Eaton myasthenic syndrome
Multifocal motor neuropathy
Myasthenia gravis
Neonatal haemochromatosis
Primary immunodeficiency diseases
Stiff-person syndrome
Graft-versus-host disease
Acute disseminated encephalomyelitis
ANCA-positive systemic necrotising vasculitis
Autoimmune haemolytic anaemia
Pemphigoid and pemphigus
Evans syndrome – autoimmune haemolytic anaemia with ITP
Fetomaternal/neonatal alloimmune thrombocytopenia
Haemophagocytic syndrome
Idiopathic (autoimmune) thrombocytopenia purpura (ITP) in children
IgM paraproteinaemic neuropathy
Kidney transplantation
Multiple sclerosis
Opsoclonus myoclonus ataxia
Post-transfusion purpura
Secondary hypogammaglobulinaemia (including iatrogenic immunodeficiency)
Specific antibody deficiency (including IgG subclasses)
Toxic epidermal necrolysis/Stevens–Johnson syndrome
Toxic shock syndrome

ADVERSE EFFECTS OF IVIG

Adverse effects occur in 3–8% of patients. Most are mild and transient, including flushing, fever, headache, fever, chills, fatigue, nausea, diarrhoea, malaise, myalgia, dyspnoea, back pain, tachycardia and hypotension. Immediate adverse effects can be effectively treated by slowing or temporary discontinuation of the infusion and symptomatic therapy with analgesics, antihistamines, and glucocorticoids in more severe reactions. IgA deficiency-related anaphylactic reactions are rare and largely preventable by identification of patients with IgA deficiency and use of IgA-depleted immune globulin.

Late adverse effects, including acute renal failure, venous thromboembolism, neutropenia, haemolytic anaemia, arthritis and aseptic meningitis, are also rare. Acute renal failure is generally transient and generally occurs in dehydrated patients and following the use of sucrose-stabilised products owing to osmotic injury. Thromboembolic complications occur as a result of hyperviscosity, especially in patients who have received a rapid infusion of high-dose IVIG and in those with risk factors including: advanced age, immobilisation,

previous venous thromboembolism, hypertension, diabetes mellitus and dyslipidaemia.[47] The blood group antibodies present in IVIG may act as haemolysins and coat red cells with immunoglobulins – resulting in a positive direct antiglobulin test (DAT) and, occasionally, haemolytic anaemia.

Haemostatic failure

Chee W Tan, Christopher M Ward and James P Isbister

Haemostasis is the process whereby blood fluidity and vascular integrity are maintained in the event of vascular injury. Failure of haemostasis is common in critically ill patients and may be complex and multifactorial in pathogenesis. As haemostatic failure may complicate a wide range of medical, surgical and obstetric disorders definitive diagnosis and specific therapy can significantly impact on outcome. Therapy may need to be initiated on clinical evidence with minimal laboratory information. Consultation with a clinical haematologist is strongly recommended.

NORMAL HAEMOSTASIS

The haemostatic system is a delicately controlled component of the host defence system, the role of which is to initiate haemostasis where and when required and in adequate, but not excessive, amounts. There has been a paradigm shift in our understanding of the haemostatic system from one of interacting humoral factors to an integrated cell-based system (**Fig. 98.1a**).[1,2] As an increasing range of focused therapies become available that modulate the activity of the haemostatic process, it is important that core aspects of the structure and function of the system are summarised.

The triad of vascular constriction, platelet plugging and fibrin clot formation to produce haemostatic plugs provides the framework for haemostasis (see Fig. 98.1a). Fibrinogen is the bulk protein of the coagulation system and fibrin is the end-product of a cascade of proteolytic activity. Thrombin is the potent proteolytic enzyme of the coagulation sequence converting fibrinogen to fibrin soluble monomers, which subsequently polymerise to form the fibrin clot. The cascade involves precursor coagulation proteins activated to become potent proteolytic enzymes, which with the aid of cofactors produce further activated precursors downstream. The polymerised fibrin is acted on by factor XIII to form a stable fibrin clot. The process of thrombin generation in small amounts initially occurs in relationship to tissue-factor-bearing cells and the process is subsequently transferred to the activated platelet surface where amplification occurs, as highlighted by the cellular model of coagulation.[2]

Following injury, vascular constriction reduces bleeding, and allows time to initiate haemostasis. With large-volume haemorrhage, the consequent systemic hypotension is an important physiological mechanism to minimise blood loss and facilitate stabilisation of the haemostatic plug. Controlled or 'tolerated' hypotension is now accepted as an important aspect of managing critical haemorrhage.[3,4] Vascular constriction is accentuated by vasoconstrictors released in association with platelet plug formation. Vascular endothelial cells play an active part by synthesising substances that act at the membrane surface and/or interact with platelets and the coagulation system (e.g. prostacyclin, antithrombin III, plasminogen activator, von Willebrand factor, thrombomodulin, heparin cofactor II and nitric oxide).[5] Following the initial vascular reactions, successful haemostasis depends on adequate numbers of functioning platelets and coagulation cascade function.

The coagulation system is now thought to be triggered predominantly via the extrinsic pathway in vivo. Damaged tissues expose tissue factor (TF), a membrane-bound protein present in cells surrounding the vascular bed. Factor (F) VII and VIIa (a small amount circulates normally in the blood) are bound to TF, activating factor X. FXa interacts with the cofactor Va to form prothrombinase complexes, with the generation of a small amount of thrombin on the cell surface. FIX is also activated by the TF/VIIa complex; it does not play a significant role in the initiation phase of coagulation, but diffuses across to platelets in the vicinity that have adhered in proximity to the site of the TF-bearing cells. FIXa binds to a specific platelet surface receptor and interacts with cofactor VIIIa, leading to activation of factor X directly on the platelet surface. This results in the amplification and propagation of coagulation. The traditional concept of the intrinsic and extrinsic systems is clearly artificial, but the concept still has value in performing and assessing haemostatic laboratory tests.

Von Willebrand factor (VWF) is a multimeric glycoprotein that mediates adhesion of platelets to the exposed subendothelium and links the primary vascular/platelet phase with coagulation by being the carrier protein for coagulant factor VIII. Factor VIII dissociates from VWF to form a complex on the activated platelet surface with IXa (tenase complex) to activate factor X to Xa. Further VWF is released from Weibel–Palade bodies in nearby endothelial cells and platelet α-granules. Platelets interact with VWF via their surface

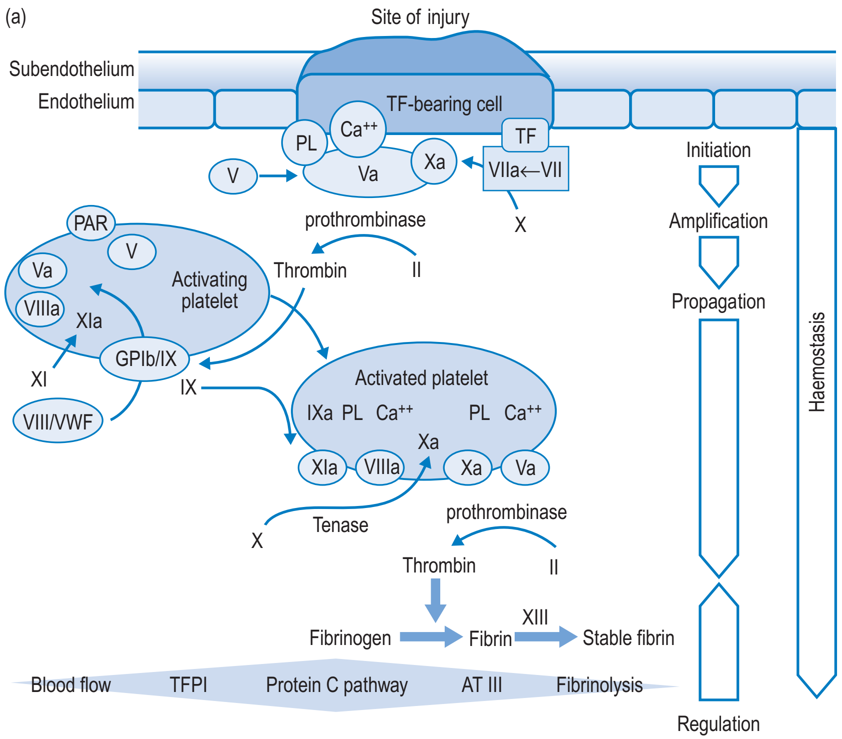

Figure 98.1 (a) The cellular model of coagulation emphasises the interplay between the endothelium, platelets and coagulation factors in the formation of a stable fibrin clot. TF=tissue factor; PL=phospholipids; PAR=protease activated receptors; TFPI=tissue factor pathway inhibitor; AT=antithrombin.

glycoprotein (GP) Ib–IX–V complexes. This results in platelet deceleration along the subendothelium, allowing platelet receptors to contact and bind collagen. Adhesion to collagen and subsequent platelet activation is now thought to be critical in haemostasis and is primarily facilitated by platelet glycoprotein VI (GPVI) and the GPIa–IIa receptor.[6,7] Recent literature suggests that GPIb–IX–V and GPVI may work in concert to mediate platelet activation, culminating in platelet aggregation via the activation of GPIIb–IIIa.[8,9]

Platelet adhesion, initiated by GPIb–IX–V binding to VWF and GPVI binding to collagen, produces a platelet monolayer over the injured subendothelium, and hence a procoagulant surface. Activation of the coagulation cascade results in local generation of thrombin, which binds to platelet protease-activated receptors (PARs), enhancing intracellular calcium mobilisation and platelet aggregation, resulting in production of a haemostatic plug and further facilitating coagulation. Further extension occurs due to platelet recruitment by platelet agonists, such as thrombin and other mediators, adenosine 5-diphosphate (ADP) and thromboxane A_2 released directly from platelets. P-selectin is expressed during activation and also plays a role in platelet-to-platelet cohesion.

Parallel to and within the coagulation system are complex feedback mechanisms to guard against inappropriate and excessive activation.[10–12] Several inhibitory proteins, including antithrombin III, thrombomodulin, protein C and S, tissue factor pathway inhibitor and in company with the fibrinolytic system, are important in controlling the degree and site of fibrin formation. Thrombin itself acts as either a procoagulant or anticoagulant depending on the context. Perturbations in this complex system can produce a wide range of clinical disorders from excessive arterial or venous thrombosis, microvascular obstruction and atheroma to haemostatic failure.

SYSTEMIC HAEMOSTATIC ASSESSMENT

There may be clinical features suggesting local or generalised failure of the haemostatic system (see **Fig. 98.1b**). Clinical history is important, especially with respect to previous bleeding, family history, co-morbid medical conditions and medications. The nature of surgery/invasive intervention may have haemostatic issues that need specific consideration.

Haemostatic system assessment can be broadly divided into laboratory tests of primary haemostasis, specifically platelet number and function, and tests of secondary haemostasis, which assess the integrity of the coagulation cascade (see Fig. 98.1b). Point-of-care haemostatic testing is increasing, particularly in the

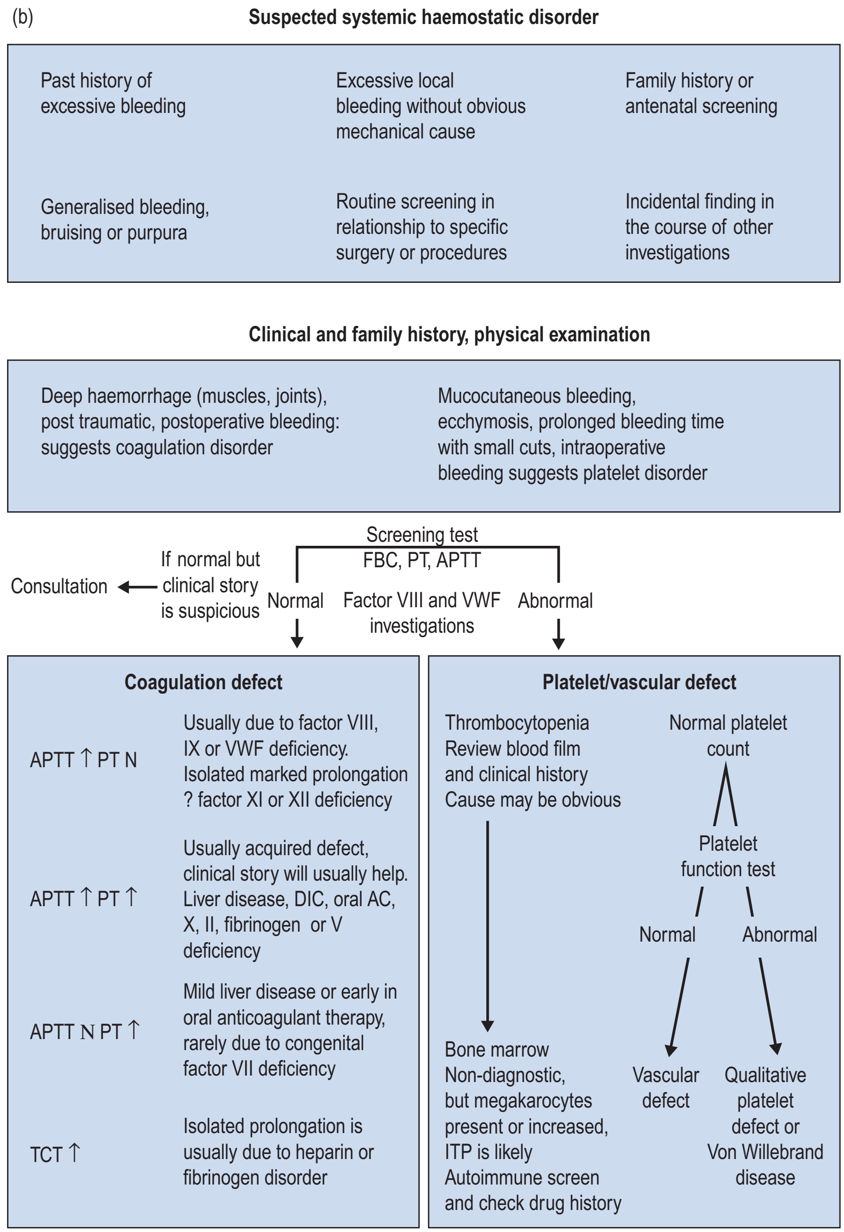

Figure 98.1, cont'd (b) Key features of history, examination and laboratory testing involved in the work-up of a patient suspected of a systemic haemostatic disorder. DIC=disseminated intravascular coagulation; AC=anticoagulants.

perioperative assessment of bleeding risk, in critical bleeding and massive blood transfusion, as well as in the assessment of bleeding risk attributable to new anticoagulant and antiplatelet therapy.

TESTS OF PRIMARY HAEMOSTASIS

A full blood count may reveal a depressed platelet count (thrombocytopenia). While a low count (less than 50×10^9/L) can contribute to haemostatic failure, a normal platelet count does not exclude platelet dysfunction as a cause of bleeding. Platelet function tests can be used both for the diagnosis of platelet disorders, and to monitor antiplatelet therapy at point of care.[13,14]

The platelet function analyser (PFA-100™) has replaced the bleeding time as a commonly used screening test for primary haemostatic defects. In the PFA-100™, citrated whole blood is subjected to high shear through a membrane coated with platelet agonists, collagen/epinephrine (adrenaline) or collagen/ADP,

resulting in platelet adhesion, aggregation and closure of an aperture present in the membrane.[15] The time to occlude the aperture is recorded as the end-point and referred to as the closure time. The technique is simple and rapid to perform, but the results may be influenced by the platelet count, haematocrit, and ABO blood group. A normal result has a high negative predictive value, and the test is also sensitive to major bleeding disorders such as VWD, Glanzmann's thrombasthenia (deficiency in GP IIb/IIIa) and aspirin use. The assay is less sensitive to milder bleeding defects such as platelet storage pool disease, variably prolonged by platelet glycoprotein IIbIIIa antagonists and not affected by clopidogrel.[16] Standard light transmission aggregometry (LTA) is the gold standard method for diagnosis of platelet function defects, but requires careful preparation of the patient and technical expertise. LTA is not useful in the critical care setting, where drugs, organ failure and other stressors are likely to affect platelet responses. The recent development of whole blood multiple electrode platelet aggregometry (WBA) such as the Multiplate (Roche) to measure platelet function is promising, as it is a simple and rapid assay with less risk of artefactual platelet activation.[17] The use of WBA in assessing platelet response to aspirin and clopidogrel, and in the diagnosis of heparin-induced thrombocytopenia has been published, with results correlating well with LTA.[18,19]

The VerifyNow™ (Accumetrics) is a point-of-care test, which measures platelet aggregation in whole blood, and has been used to gauge response to aspirin, clopidogrel and glycoprotein IIbIIIa antagonists. A large randomised trial (GRAVITAS) utilised VerifyNow to individualise clopidogrel dose in over 2000 patients post percutaneous coronary intervention (PCI) with drug-eluting stents, with measured end-points including moderate/severe bleeding.[20] Flow cytometry is another emerging technology that may become useful in the critical care setting, with the advantages of low sample volume, and availability of testing of whole blood, representing physiological conditions.[21,22] An application of flow cytometry applicable to platelet function testing is the phosphorylation of vasodilator-stimulated phosphoprotein (VASP), which is used to assess the response to P_2Y_{12} antagonists such as clopidogrel.[23]

TESTS OF SECONDARY HAEMOSTASIS

In most clinical settings, a full blood count, prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen level, D-dimer ± thrombin clotting time (TCT) provide a broad screen for most clinically significant haemostatic disorders (see Fig. 98.1b).[24–26] Based on these results, further specific tests of haemostasis may be performed (e.g. mixing studies, factor assays, platelet function tests and test of fibrinolytic function).

Broadly speaking, the PT tests the extrinsic system, the APTT the intrinsic system, and the TCT fibrinogen conversion. The D-dimer assay measures the breakdown products from lysis of fibrin, and serve as evidence that both fibrin generation and fibrinolysis have been triggered.

PROTHROMBIN TIME (PT)

The PT is a test of the extrinsic coagulation and prolongation may be caused by factor VII deficiency, liver disease, vitamin K deficiency or oral anticoagulant therapy. The PT is also expressed as the international normalised ratio (INR), specifically used to monitor anticoagulant use.

ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)

The APTT is a test of the intrinsic coagulation system and the result must be interpreted with caution. There may be significant variation in test sensitivity and specificity between laboratories. In unselected patients there is poor correlation between the APTT prolongation and either the presence of haemostatic failure or the likelihood of a patient bleeding. Uncommonly a lupus anticoagulant may prolong the APTT and represent a prothrombotic state, rather than a bleeding tendency. In a patient with a suspected systemic haemostatic defect, an isolated prolongation of the APTT may represent:

- deficiency or an inhibitor of factor VIII, IX or XI
- deficiency in the contact phase of the coagulation cascade (i.e. FXII and prekallikrein, which importantly does not result in clinically significant bleeding)
- prolongation of both APTT and PT may be due to deficiencies of factors X, V, prothrombin or fibrinogen.

THROMBIN CLOTTING TIME (TCT)

This is a test of the final conversion of fibrinogen to fibrin. Prolongation of TCT is due to hypofibrinogenaemia, dysfibrinogenaemia, heparin, or generation of fibrin degradation products.

D-DIMER

The D-dimer assay measures cleavage fragments resulting from the proteolytic action of plasmin on fibrin, so is specific for fibrinolysis and not primary fibrinogenolysis. Elevation of D-dimer may be seen in the postoperative state, trauma, renal impairment, sepsis and venous thrombosis. High levels of D-dimer can occur with excessive fibrinolysis, as seen in disseminated intravascular coagulation.

SPECIFIC COAGULATION FACTOR ASSAYS

Fibrinogen is commonly measured in patients suspected of systemic haemostatic failure, using clottable protein methods, end-point detection techniques, or

immunochemical tests. The Clauss method is the most common fibrinogen assay used.

Specific factor assays can be performed as secondary tests, after initial screening tests such as the APTT reveal abnormalities. With an isolated prolonged APTT, a mixing test, in which plasma from normal donors is added to patient sample plasma, can be performed. It will correct APTT prolongation secondary to factor deficiencies, but not if the prolongation is due to coagulation inhibitors. Non-specific inhibitors include drugs such as heparin and lupus anticoagulants; specific inhibitors such as acquired antibodies to FVIII are rare. An APTT corrected by a mixing test is further investigated with specific assays for FVIII, FIX and FXI. An isolated PT is investigated in a similar fashion, with FVII deficiency/inhibitor a possible cause.

EUGLOBULIN LYSIS TIME (ELT)

This test mainly reflects the presence of plasminogen activators and if shortened is indicative of system fibrinolytic activation.

GLOBAL COAGULATION ASSAYS

The PT and APTT, although useful in detecting coagulation factor deficiencies, have drawbacks and the APTT in particular does not accurately reflect haemostasis in vivo. Haemostasis does not just involve coagulation factors, but also cellular components including platelets and endothelial cells that play integral roles, so there is inevitably a limited assessment of coagulation profile via these tests. Global coagulation assays hence offer the advantage of assessing the haemostatic system as a whole, involving both coagulation factors and cellular components, and, as results are individualised, offer the potential of individualised treatment depending on the result.[27] Point-of-care testing with global coagulation assays offers significant advantages in the critical care setting. Global coagulation testing includes thrombin generation assays and whole blood thromboelastography.

Thrombin generation assays measure the final step of the coagulation pathway. They inform on both the bleeding risk and hypercoagulability of a patient, as thrombin has both prothrombotic and fibrinolytic roles. The calibrated automated thrombogram (CAT) assesses thrombin generation by using fluorogenic substrates.

Several studies have shown attenuated thrombin generation in patients with haemophilia and FXI deficiency with a severe clinical bleeding phenotype, independently of FVIII/FIX levels.[28,29] Thrombin generation was also reported to correlate with clinical response to bypassing agents such as recombinant factor VIIa (rFVIIa) in patients with severe haemophilia with high-titre inhibitors in the perioperative setting.[30] These assays appear promising for clinical use, but require specialised equipment and are still largely restricted to research settings at present.

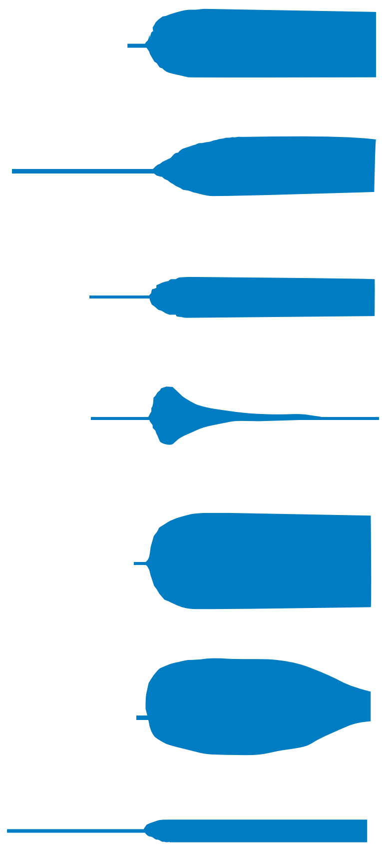
TEG® and ROTEM® are both methods of whole blood thromboelastography used to assess haemostasis, particularly in the perioperative period as a point-of-care test. Both TEG and ROTEM enable ongoing evaluation of a clot as it forms. In both methods, a sample is placed in a cup, with a pin present in the centre of the cup as the device is operating. In the TEG the cup is spinning, whereas in the ROTEM it is the pin that rotates. The formation of a clot results in reduced movement of the pin, with the information translated into computer tracings such as that depicted in **Figure 98.2**.

Figure 98.2 illustrates the utility of the TEG and ROTEM to provide information on all stages of haemostasis, including fibrinolysis and clot stability, via challenge with tissue plasminogen activator. Both TEG and ROTEM have been widely used in liver transplantation and in cardiac bypass surgery in particular. It can also be utilised in clinical settings where changes in haemostasis can occur rapidly, with high bleeding risk, likely concomitant use of anticoagulants, frequent use of blood transfusion and likelihood of multi-organ failure and disseminated intravascular coagulation. Serial monitoring with thromboelastography has been used for haemostatic assessment of critically ill patients and has guided clinical management, including use of tranexamic acid and FXIII.[31,32] Thromboelastography results have also correlated with both clinical bleeding phenotype and response to bypassing agents, such as rFVIIa, in patients with haemophilia and inhibitors.[33,34] As they provide a more comprehensive clinically relevant assessment of the haemostatic status at point of care, it is likely that the use of global coagulation assays will increase.

CONGENITAL HAEMOSTATIC DEFECTS

Congenital bleeding disorders are rare, but should be suspected in the clinical setting with discrepant or unexpected major bleeding or with abnormal laboratory results (i.e. an isolated prolonged APTT). It is important to identify the defect so that specific replacement therapy can be administered, with dosage guided by regular coagulation factor level monitoring. Congenital bleeding disorders include haemophilia A (FVIII deficiency), haemophilia B (FIX deficiency) and von Willebrand disease. Haemophilia A and B are characterised by musculoskeletal and soft-tissue bleeding. Apart from specific factor concentrates, antifibrinolytics such as tranexamic acid are useful adjunctive therapy (discussed later in this chapter), with desmopressin also effective therapy in mild haemophilia A and certain types of vWD by stimulating endogenous release of FVIII and VWF.

Congenital platelet disorders are also rare, the commonest severe disorder being Glanzmann's thrombasthenia, which is a deficiency or dysfunction of GPIIbIIIa.[35] A history of repeated mucocutaneous bleeding



Clinical state	Parameter changes
Normal	Normal
Anticoagulants, factor deficiency	Increased R, K Decreased α
Thrombocytopenia, platelet blockers	Decreased MA
Fibrinolysis	Increased LY30, R Decreased MA, α
Hypercoagulable state	Decreased R, K Increased MA, α
Early DIC, hypercoagulable and secondary fibrinolysis	Decreased R, K Increased MA, α, LY30
Late DIC, hypocoagulable	Increased R, LY30 K not reached Decreased MA, α

Figure 98.2 Comparative thromboelastograph tracings in normal and pathological states, with measured parameters assessing different aspects of haemostasis. These include: R time, which is the time elapsed until initial fibrin formation; K time gauges the dynamics of clot formation, α-angle assesses the kinetics of fibrin accumulation and cross-linkage, MA (maximum amplitude) assesses the effectiveness of platelet–fibrin interactions, while lysis time assesses fibrinolysis. *(Modified from Srinivasa et al.[65])*

with an abnormal PFA-100 test result may be suggestive of such disorders. Platelet transfusions may be required for acute bleeds or in relation to elective surgery; desmopressin acetate (DDAVP) ± antifibrinolytic therapy and rFVIIa may all have a role in management.

ACQUIRED HAEMOSTATIC DISORDERS

The acquired disorders of coagulation are usually more complex and multifactorial than the hereditary disorders. A unified approach is essential for the successful management of these potentially life-threatening situations, and transfusion therapy cannot be isolated from other treatment. Acquired haemostatic defects are commonly seen in extracorporeal circulation cardiac surgery and, like congenital abnormalities, can also be broadly divided into platelet defects and abnormalities involving coagulation factors.

EXTRACORPOREAL CIRCULATION CARDIAC SURGERY

Extracorporeal circulation, especially cardiopulmonary bypass, is associated with a range of haemostatic disturbances and the risks of bleeding versus thrombosis must be constantly balanced.[36] Time on bypass and multiple-valve replacements or reoperations impact on this risk. Haemostatic failure usually becomes apparent in the operating room or soon after and appropriate laboratory investigations should be performed. Plasma products or platelets will be less effective if anticoagulants such as heparin have not been adequately reversed. Increased fibrinolytic activity may in some cases also contribute to bleeding.

QUANTITATIVE PLATELET DEFECTS

DRUG-INDUCED THROMBOCYTOPENIA

The clinical presentation of drug-induced thrombocytopenia ranges from dramatic and fulminant with marked haemostatic failure to minor abnormalities. Drugs with a predilection for inducing thrombocytopenia include quinine (also in bitter drinks), quinidine, antituberculous drugs, heparin, thiazide diuretics, penicillins, sulfonamides, rifampicin and anticonvulsants.

Heparin-induced thrombocytopenia (HIT) is an important and potentially life-threatening complication of heparin therapy.[37–39] An immune reaction to heparin typically occurs after 7–10 days of therapy, leading to platelet aggregation and thrombocytopenia. The thrombocytopenia seen in HIT is often only moderate, and platelet numbers may remain within the normal range. In contrast to other causes of drug-induced thrombocytopenia, this condition is not associated with bleeding, but rather represents a prothrombotic state, with potentially devastating arterial, microvascular or venous thrombosis associated with the resultant platelet aggregation. Medical staff must be vigilant to the possibility of HIT occurring, and to keep heparin therapy as brief as possible. The incidence is less with the use of low-molecular-weight heparin (LMWH), but a strong clinical suspicion of HIT (probability of HIT based on four criteria of the 4T score: timing and nadir of the thrombocytopenia, the presence of thrombosis, and the possibility of other causes accounting for the thrombocytopenia – see **Table 98.1**) should result in the cessation of unfractionated heparin (UFH)/LMWH, and commencement of an alternate anticoagulant, such as danaparoid or thrombin inhibitors such as argatroban and lepirudin, while awaiting laboratory results.[40]

HIT can be challenging to diagnose in the critical setting, particularly with many potential causes of thrombocytopenia coexisting in the same clinical scenario. New scoring systems for HIT have emerged to address this issue.[41] Several screening tests for heparin–platelet factor 4 antibodies are available, but these also detect non-pathogenic antibodies, which can occur commonly in the setting of cardiac surgery. 'Functional' HIT assays, such as the serotonin release assay or whole blood aggregometry,[18] which show platelet activation in the presence of heparin and patient serum/plasma can confirm a diagnosis of HIT but are performed only in reference laboratories.

THROMBOTIC THROMBOCYTOPENIC PURPURA/HAEMOLYTIC URAEMIC SYNDROME

Thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome (TTP/HUS) comprises disorders characterised by haemolytic anaemia and thrombocytopenia, with evidence of microangiopathy as suggested by the presence of red cell fragments on the blood film. While TTP and HUS can be difficult to distinguish from each other clinically, reduced activity of the vWF-cleaving protease ADAMTS13 is diagnostic of TTP, due to either an autoantibody or a congenital deficiency. Importantly, TTP/HUS can be distinguished from DIC by the absence of abnormal coagulation testing. TTP can also be associated with use of medications such as clopidogrel and quinine, and in settings such as pregnancy and bone marrow transplantation. This condition and its management are discussed in more detail in Chapter 97.

IDIOPATHIC THROMBOCYTOPENIC PURPURA (ITP)

ITP is an autoimmune disorder where autoantibodies (IgG) are directed against platelets, which are subsequently destroyed by the monocyte–macrophage system, predominantly in the spleen. ITP remains a diagnosis of exclusion, and is typically a disease of children and young adults. Corticosteroids should generally be regarded as short-term therapy in acute flares of this condition, particularly if the platelet count were to

Table 98.1 4T score to assess clinical probability of HIT; a score of 0–3 represents low probability, 4–5 intermediate and 6–8 high clinical probability of HIT

CATEGORY	2 POINTS	1 POINT	0 POINT
Thrombocytopenia	>50% fall, or nadir $\geq 20 \times 10^9$/L	30–50% fall, or nadir 10–19 $\times 10^9$/L	<30% fall, or nadir $<10 \times 10^9$/L
Timing of the decrease in platelet count	Days 5 to 10, or ≤day 1 with recent heparin (past 30 days)	>Day 10 or timing unclear, or <day 1 if heparin exposure within past 30–100 days	<Day 4 (no recent heparin)
Thrombosis or other sequelae	Proven thrombosis, skin necrosis, or acute systemic reaction after heparin bolus	Progressive, recurrent, or silent thrombosis; erythematous skin lesions	None
Other causes of thrombocytopenia	Non evident	Possible	Definite

Modified from Lo et al.[40]

fall to <10 000/μL +/− bleeding. In adults, the majority of patients respond with a rise in the platelet count. An initial high dose (1 mg/kg) of prednisolone a day is given until response occurs, after which the dose is gradually reduced. High-dose intravenous immunoglobulin is effective in most patients and is specifically indicated in fulminant acute disease resulting in major bleeding and/or not responding to corticosteroids, and is particularly useful preoperatively and in pregnancy. Platelet transfusions should be reserved for major, life-threatening bleeding.

Options for management of chronic ITP have increased recently with the availability of medications such as romiplostim that stimulate platelet production via binding to receptors for thrombopoietin, which is the primary regulator of both megakaryopoiesis and platelet production. Targeting pathogenic antibodies with rituximab has also shown some efficacy in ITP.

THROMBOCYTOPENIA IN CRITICAL CARE SETTINGS

Platelets play an important role in the inflammatory response and a reactive thrombocytosis is usually seen in infection. However, if there is overwhelming sepsis, associated disseminated intravascular coagulation (DIC) or marrow suppressive influences, thrombocytopenia can be seen. Sepsis, shock, DIC, alcoholism and nutritional deficiency are common factors contributing to thrombocytopenia in critically ill patients. Thrombocytopenia also often occurs in cardiothoracic surgery after extracorporeal blood circulation.

QUALITITATIVE PLATELET DEFECTS

The most common cause of acquired platelet dysfunction seen in the critical care setting is the use of antiplatelet therapy, which is discussed later in the chapter. Other causes of platelet dysfunction include uraemia, hepatic cirrhosis, multiple myeloma and myeloproliferative disorders. Platelet dysfunction can also occur post cardiac-bypass surgery, and can result in bleeding in the presence of a normal or near-normal platelet count. In this setting, platelet transfusions are administered, and antifibrinolytics are useful as adjunctive therapy.

CRITICAL HAEMORRHAGE AND MASSIVE BLOOD TRANSFUSION

The nature and management of haemostatic defects secondary to acute and/or massive blood loss are explained in greater detail in a preceding chapter. There has been increasing interest in the role of fibrinogen and the use of specific fibrinogen in trauma as part of a massive transfusion protocol. More recent guidelines have suggested that fibrinogen concentrations exceed 1.5 g/L to maintain haemostasis, compared with 1 g/L, with higher levels targeted in specific populations, such as cardiac surgery (3.9 g/L).[42]

Fresh frozen plasma (FFP) and platelet concentrates are often infused to correct significant coagulopathy in massive bleeding. However, the efficacy of FFP has not been established in such settings, including cardiac surgery.[43] FFP also carries the risk of bacterial and viral infections, incompatibility reactions, transfusion-related acute lung injury (TRALI) and fluid overload. Concerns over variant Creutzfeldt–Jakob disease have led to recommendations to cease FFP derived from the UK. Cryoprecipitate use, which is a source of fibrinogen, has been withdrawn in many countries of the European Union. Fibrinogen concentrates, on the other hand, are virally inactivated and carry a lower risk of transmitting infection, are not blood group specific, and can be stored at room temperature and given without delay owing to thawing. The use of fibrinogen concentrates in a wide variety of clinical settings in which bleeding risk is high, including aortic aneurysm graft surgery and coronary bypass graft surgery, has resulted in a significant reduction in blood product support (FFP, platelets, RBCs), correction of laboratory abnormalities in coagulation and significant reduction in perioperative bleeding.[42–44] In these studies, fibrinogen dose was guided by thromboelastography, emphasising the utility of global coagulation assays in guiding clinical management of patients with massive blood loss. ROTEM and TEG provide real-time assessment of the viscoelastic properties of clot formation whereas fibrinogen levels, although they can be used to guide administration of fibrinogen concentrates, are not known immediately hence do not reflect current haemostatic status. Larger prospective trials are required before the role of fibrinogen concentrates in the treatment of massive bleeding can be clearly defined, but results so far have been promising.

HAEMOSTATIC FAILURE ASSOCIATED WITH LIVER DISEASE

The liver is the production site of nearly all the coagulation factors involved, apart from FVIII and VWF. Bleeding is challenging to evaluate in patients with liver impairment, with prohaemostatic changes (including reduced levels of natural anticoagulants and plasminogen) and antihaemostatic changes (thrombocytopenia, platelet dysfunction, impaired synthesis of clotting factors, excessive fibrinolysis) likely to coexist. Mild to moderate prolongation of PT does not correlate with bleeding risk. Recent guidelines have advised assessing FFP use prior to invasive procedures, based on individual patient characteristics.[45,46] FFP also carries the theoretical risk of increasing portal pressure and aggravating bleeding. Prothrombin complex concentrates (PCCs) are a viable alternative, particularly in patients with fluid overload.[47] Haemostatic defects due to deficient vitamin-K-dependent coagulation factors (in patients with predominantly cholestatic liver disease)

may be rapidly reversed with vitamin K therapy, and plasma transfusion may not be required.

Hypofibrinogenaemia and dysfibrinogenaemia are common in patients with liver impairment. As discussed previously, cryoprecipitate, and more recently, specific fibrinogen concentrates, can be administered in patients with chronic liver disease and bleeding with fibrinogen levels <1.5 g/L, or in patients not responding to plasma transfusion, as dysfibrinogenaemia is likely to be present in this setting.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Disseminated intravascular coagulation is a pathophysiological process characterised by an inappropriate, excessive and uncontrolled activation of the haemostatic process. The perpetuation of the process may be due to continuation of the stimulus and/or consumption of the natural inhibitors of haemostasis. Initially adequate compensation results in defects being demonstrable only in the laboratory tests, but if the initiating disorder is severe the clinical syndrome of uncontrolled acute DIC can result in significant bleeding, usually associated with end organ failure. A compensatory secondary fibrinolysis occurs, which in some cases may accentuate the bleeding.

PATHOPHYSIOLOGY

DIC is characterised by the initial consumption of clotting factors and platelets within the circulation, resulting in varying degrees of microvascular obstruction due to fibrin deposition (see **Fig. 98.3**). When significant platelet and coagulation factor consumption occurs, bleeding may become a major feature.

Mechanisms that may inappropriately activate the haemostatic system include:

- activation of the coagulation sequence by release of tissue thromboplastins into the systemic circulation (e.g. following extensive tissue trauma, during surgery, malignancy and during acute intravascular haemolysis)
- vessel wall endothelial injury causing platelet activation followed by activation of the haemostatic system (e.g. Gram-negative sepsis from endotoxin release, viral infections, extensive burns, prolonged hypotension, hypoxia or acidosis, see **Box 98.1**)
- induction of platelet activation (e.g. septicaemia, viraemia, antigen–antibody complexes).

CLINICAL FEATURES

The clinical presentation of DIC varies, with patients showing thrombotic, haemorrhagic, or mixed manifestations in various organ systems. The major clinical problem and presenting feature of acute DIC is bleeding. This may manifest as generalised bruising, or bleeding at sites of therapeutic or traumatic invasion (venepuncture sites and surgical wounds). DIC may occur in association with a wide range of clinical disorders (see Box 98.1). When DIC occurs in acutely ill patients with multisystem organ failure the prognosis is poor.

Box 98.1 Conditions associated with disseminated intravascular coagulation

Infection	Severe allergic reaction
Bacterial sepsis	Drug reactions
Viral haemorrhagic fevers	Extracorporeal circulations
Protozoal (malaria)	Snake bite envenomation
Trauma	Vascular disorders
Extensive tissue injury	Giant haemangioma
Head injury	Aortic aneurysm
Fat embolism	Pregnancy associated:
Malignancy	Septic abortion
Carcinoma	Abruptio placentae
Leukaemia (especially promyelocytic)	Eclampsia
	Amniotic fluid embolism
Immunological disorders	Placenta praevia
Transplantation rejection	Burns
Incompatible haemolytic blood transfusion reactions	Hyperthermia
	Liver disease and acute hepatic necrosis

LABORATORY FINDINGS

Results of tests may be variable and difficult to interpret. Significant DIC can be present despite normal standard coagulation tests (i.e. PT, APTT and TCT). The key tests in diagnosis are those that provide evidence for excessive conversion of fibrinogen to fibrin within the circulation and its subsequent lysis. Platelet–fibrin clots create a mesh in the microcirculation in which passing red cells may be traumatised, resulting in red cell fragmentation and haemolysis. The blood film may demonstrate fragmentation of the red cells (microangiopathic haemolytic anaemia), but this is more commonly seen in chronic DIC, especially in association with malignancy.

The diagnosis is usually based on a combination of the appropriate clinical picture with a supportive pattern of laboratory tests of the haemostatic system (**Table 98.2**).[48] Thrombocytopenia, hypofibrinogenaemia, with prolongation of the APTT, PT and TCT in conjunction with an elevation of fibrin degradation products (D-dimer test), is supportive evidence for the diagnosis. More specialised tests such as elevation of fibrinopeptide A and reduced levels of antithrombin III add further weight to the diagnosis. To assist in the accurate diagnosis of DIC, the International Society on Thrombosis and Haemostasis (ISTH) has developed a scoring algorithm based on laboratory results (**Table 98.3**).

In chronic DIC the laboratory findings are different from acute DIC. Many of the usual tests of haemostasis are normal or near normal. However, this is a

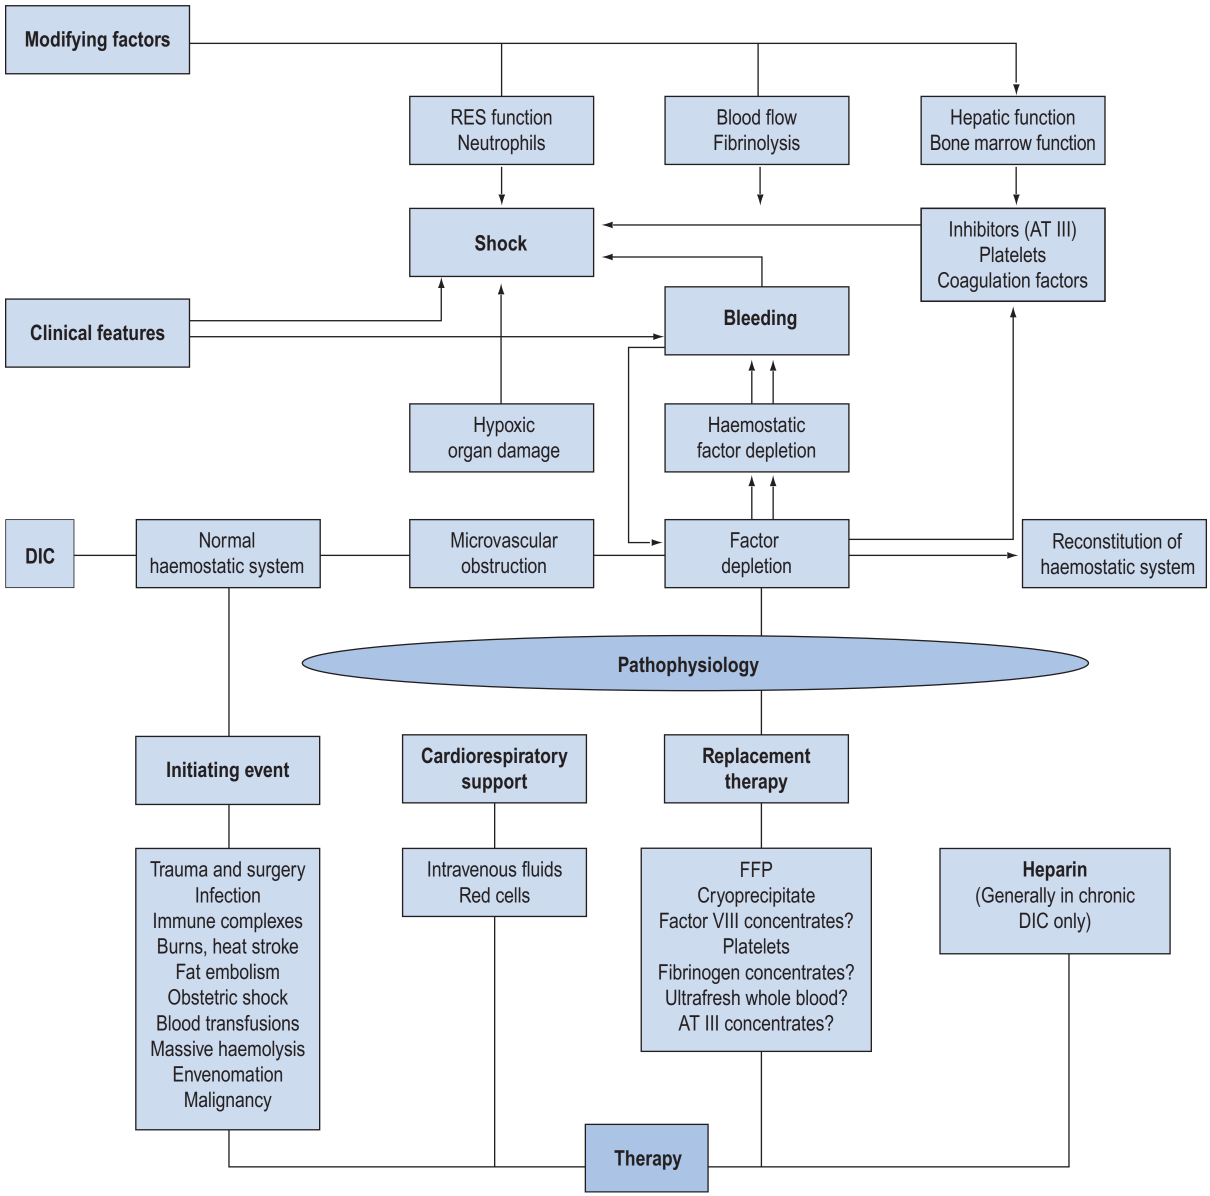


Figure 98.3 The pathophysiology and management of disseminated intravascular coagulation (DIC). RES=reticulo-endothelial system; AT=antithrombin.

compensated state in which there is increased turnover of each of the haemostatic components. D-dimer is elevated in this setting and a microangiopathic red cell picture is often seen on the peripheral blood film.

THERAPY

The most important measure in the management of DIC is treatment of the initiating cause in conjunction with general resuscitation. Blood component therapy should be given only in patients with bleeding or prior to major invasive procedures. Local institutions routinely establish laboratory parameters to guide transfusion therapy, usually aiming to maintain fibrinogen levels >1–1.5 g/L and platelet counts >20-30×10^9/L, maintaining around 50×10^9/L and PT below 1.5 times normal. Transfusion of blood products has the theoretical risk of ‘feeding the fire’, providing substrates for microthrombi formation, potentially leading to multi-organ failure. Heparin should be used judiciously in the setting of DIC, and can be beneficial in settings where major thrombotic complications have occurred, rather than bleeding. Small doses of UFH should be used initially. Therapeutic exchange can be considered in severe DIC, in which fluid overload has

occurred, as activated coagulation factors and pro-inflammatory cytokines are removed in the process. There have also been reports in the literature regarding the use of antithrombin in the setting of DIC, with varying impact on patient mortality.[49] There are currently no randomised controlled trials regarding the efficacy of rFVIIa in the setting of DIC.

ANTITHROMBOTIC THERAPY

There are an increasing number of antithrombotic agents available and associated with wider clinical use there has been a resultant increase in iatrogenic bleeding in patients presenting with other co-morbidities (e.g. trauma, surgery and invasive procedures). Intensivists must be aware of the methods for rapid reversal of therapy.[50,51] Bleeding problems in patients on well-controlled anticoagulation are usually due to surgery, trauma or a local lesion (e.g. peptic ulceration). Otherwise, bleeding can be due to over-anticoagulation, sometimes as a result of drug interactions. Elective surgery in this group of patients needs careful planning if haemorrhagic and thrombotic complications are to be avoided. Patients on antithrombotic therapy involved in traumatic events are a challenge in whom there is the risk of progression of the original insult, increased risk of post-traumatic complications, and mortality.

VITAMIN K ANTAGONISTS

These agents, including warfarin, induce a functional deficiency of the vitamin-K-dependent clotting factors (II, VII, IX and X), the anticoagulant action being measured by prolongation of PT (INR). The indications for reversing vitamin K antagonists depends on the clinical indication for therapy. Warfarin is now used increasingly in stroke prevention in the setting of atrial fibrillation. Reversal of over-anticoagulation should occur in most patients with an INR over 5, in bleeding patients, or in those at high risk of bleeding. In most cases oral anticoagulation can be ceased temporarily without further intervention. Vitamin K will reverse the warfarin effect as new factors are synthesised – for more rapid reversal, prothrombin complex concentrates (PCCs) should be used. PCCs have emerged as an effective alternative to FFP, to rapidly reverse the anticoagulant effects of warfarin, including protein C correction. Recent publications in the literature have advocated PCCs for urgent reversal of vitamin K antagonists, and several studies recommend PCCs, instead of FFP, for reversal in neurological emergencies.[52,53] PCCs provide important advantages over FFP, including viral inactivation, reduced risk of fluid overload, lack of a need for a cross-match, and also no risk of TRALI (transfusion-associated acute lung injury). There is as yet no definite consensus on optimal dosing of PCCs. They may carry an increased risk of thromboembolic events.

Vitamin K_1 is essential for sustained reversal, but care must be taken not to give an excessive dose if the patient needs to return to oral anticoagulation in the long term. For most surgical interventions or invasive procedures an INR of 1.5 or less is acceptable. This can usually be achieved by temporarily ceasing warfarin. If urgent reversal with vitamin K is required, the injectable form is preferred to oral administration in view of its more rapid onset of action. Doses of up to 5 mg of vitamin K can reverse the INR prolongation without causing significant warfarin resistance when the drug is resumed.

HEPARINS

Heparins act by potentiating the action of antithrombin III, a natural coagulation inhibitor. Unfractionated heparin (UFH) neutralises both thrombin and FXa, in contrast to the LMWHs, which predominantly neutralise FXa. The anticoagulant effect of UFH is usually measured by prolongation of the APTT. LMWHs do not prolong the APTT and are generally administered on weight basis and are not routinely monitored by a laboratory test. When monitoring is required, a drug-specific anti-Xa assay can be used.

Similar to over-anticoagulation with warfarin, cessation of heparins may be sufficient if bleeding occurs. If major bleeding has occurred, immediate reversal of UFH activity can be achieved with protamine sulphate. Protamine itself can paradoxically act as an anticoagulant in excess doses, hence doses of protamine required to neutralise 80% of estimated circulating UFH (e.g. 1 mg protamine sulphate will neutralise 100 units of heparin given in the previous 2–3 hours) have been suggested.[47] Protamine sulphate should be injected slowly by the intravenous route. Bleeding on LMWH is more difficult to manage than UFH, owing to the longer effective half-life – protamine also only partially reverses the LMWH effect (1 mg for each 1 mg enoxaparin in previous 8 hours).

ANTIPLATELET AGENTS

Antiplatelet agents are used widely for the treatment of arterial disease, and many of the non-steroidal anti-inflammatory agents are also platelet-inhibitory drugs. Aspirin has an irreversible effect on platelet function and platelet function tests may show abnormalities for up to 10 days after medication. Most of the other non-steroidal anti-inflammatory drugs have a reversible effect lasting a matter of hours or occasionally days. Perioperative bleeding is usually mild, but occasionally may be serious, depending on the surgery, and in some situations a platelet transfusion may be necessary.

Agents such as clopidogrel act as inhibitors of platelet aggregation by inhibiting the binding of ADP to its platelet receptor P2Y12, thus suppressing ADP-mediated activation of the GPIIb/IIIa complex. Prasugrel, another ADP antagonist, has emerged as effective therapy for ACS in the setting of PCI when combined with aspirin. Ticagrelor, which antagonises ADP via a different binding site to clopidogrel and prasugrel, is another treatment option. As with aspirin, platelets exposed to ADP antagonists are affected for their lifespan and recovery of normal platelet function occurs as new platelets are produced. ADP antagonists are thought to be more potent than aspirin in antiplatelet effect and hence associated with higher bleeding risk.[54] Prasugrel achieves more predictable antagonism of ADP compared with clopidogrel, at the expense of increased bleeding.[55] The bleeding risk is also high with ticagrelor.[56] The bleeding risk associated with antiplatelet agents has also increased with more frequent use of dual antiplatelet therapy, particularly with the advent of drug-eluting coronary stents and the risk of late in-stent thrombosis.

Antiplatelet agents have a central role in preventing arterial thrombosis. Clinicians are now regularly confronted by balancing the haemorrhagic risks associated with these agents, especially in the perioperative setting, against the thrombotic risks associated with their discontinuation. Platelet transfusions are the mainstay of treatment to reverse the effects of antiplatelet therapy when major bleeding occurs. Aspirin is considered less potent than ADP antagonists in terms of bleeding risk. Hence, it is generally agreed that continuing acetylsalicylic acid during vascular surgery procedures and in most other settings in which the bleeding risk is likely to be low is acceptable, with platelet transfusions administered only in high-risk settings, such as neurosurgery or eye surgery. There should be a lower clinical threshold to administer platelets for reversal of the more potent ADP antagonists, particularly prasugrel. It is generally recommended that ADP antagonists, such as clopidogrel, be ceased 5 days before surgery to allow regeneration of the platelet pool. Although withdrawal of the competitive GPIIb/IIIa inhibitors at the beginning of surgery will decrease the risk of bleeding, it should be emphasised that thrombotic events in patients waiting for urgent myocardial revascularisation are a significant risk and acceptance of perioperative bleeding risk may take priority in certain scenarios. The antiplatelet effect of abciximab lasts for days, whereas normal platelet function is restored within 4–6 hours with tirofiban. Hence withdrawal of tirofiban may be sufficient in bleeding episodes in the absence of thrombocytopenia. Apart from platelet transfusion, desmopressin and rFVIIa are suitable considerations in the management of major bleeding attributable to antiplatelet therapy.

NOVEL ORAL ANTICOAGULANTS (NOACs)

Newer anticoagulants specifically targeting thrombin (dabigatran, bivalirudin, lepirudin, argatroban) or factor Xa (rivaroxaban, fondaparinux, apixaban) have emerged in the management of both arterial and venous thromboembolism and have been shown to be

Table 98.4 Pharmacological properties of new anticoagulants and antiplatelet medications

	DABIGATRAN	RIVAROXABAN	APIXABAN	PRASUGREL	TIGACRELOR
Target	Thrombin	Factor Xa	Factor Xa	Platelet P2Y12 receptor	Platelet P2Y12, different binding site to ADP

Direct antidote	No	No	No	No	No

efficacious and safe in these settings.[57,58] They offer significant advantages over vitamin K antagonist therapy, with fixed dosing, fewer drug and dietary interactions, and do not require routine laboratory monitoring (**Table 98.4**).

However, like all antithrombotic therapies, these agents have the potential to cause bleeding complications but, unlike warfarin, few have antidotes or reversal agents. Currently, there is little peer-reviewed literature regarding emergent reversal of the new anticoagulants, of which dabigatran and rivaroxaban are the most widely used. While experience grows, consensus and expert opinion emphasise the importance of risk stratification and general supportive measures depending on the degree of bleeding of patients on these anticoagulants.[59–61] Minor bleeding can be managed with withdrawal of the medication. Identification of a bleeding source and local measures to control the bleeding (which may be achieved via surgical or radiological means) are important, as are regular clinical monitoring, fluid resuscitation and red blood cell transfusions in major or life-threatening bleeding. Fluid replacement and maintenance of good urine output are particularly relevant with dabigatran, which is primarily renally excreted.

Laboratory monitoring with APTT and PT cannot provide precise information on drug levels of these agents on which to make clinical decisions. More research is required to confirm their utility in bleeding attributable to rivaroxaban or dabigatran, but a normal APTT (dabigatran) or PT (rivaroxaban) in this setting would suggest that haemostatic function is preserved, and that the NOAC is unlikely to be contributing significantly to major bleeding. Drug-specific assays for the NOACs are emerging, and will become more widely available in the near future.

It has been suggested that oral activated charcoal ingestion may be useful within 2 hours of dabigatran administration.[62] In extreme cases, acute haemodialysis or haemoperfusion can be considered in patients suspected of dabigatran overdose, especially if there is coexistent renal failure. There are currently no data on the use of oral activated charcoal in human studies with rivaroxaban, and haemodialysis would likely be ineffective in the setting of rivaroxaban overdose as it is a highly protein-bound drug.

There is no consensus on the use of FFP or PCCs in bleeding attributable to the newer anticoagulants. Abnormal laboratory parameters as a result of rivaroxaban (e.g. PT) were reversed by the administration of 4-factor PCCs in a cohort of healthy volunteers (4-factor PCCs contain similar amounts of non-activated thrombin, FVII, FIX and FX; 3-factor PCCs contain similar amounts of non-activated thrombin, FIX, and FX, but contain less FVII).[63] Such a finding was not reproduced in healthy individuals taking dabigatran. It is not known whether such findings can also be related to reversing bleeding in patients on these new anticoagulants. Furthermore, 4-factor PCCs are not routinely available in many countries including the USA and Australia.

Currently, the effectiveness of rFVIIa in reversing bleeding complications attributable to the new anticoagulants in humans is unclear and data from animal models are conflicting.[59] It has been postulated that rFVIIa acts proximally to FXa and thrombin, and hence may not alleviate the coagulopathy attributable to these new agents. rFVIIa is also prothrombotic and hence it must be used cautiously in all patients with an indication for anticoagulants.

The effectiveness of PCCs and rFVIIa for bleeding attributable to rivaroxaban and dabigatran will become clearer as familiarity with the use of both drugs increases. Currently, supportive care and local measures are the mainstays of management, with PCCs and rFVIIa a reasonable consideration in dire clinical situations, particularly if the last dose of newer anticoagulants is less than 12 hours.

ANTIFIBRINOLYTICS

Antifibrinolytic drugs such as tranexamic acid (TXA) and epsilon aminocaproic acid (EACA) are useful adjunctive drugs in the setting of major bleeding. TXA and EACA are lysine analogues, and work by competitive binding of lysine binding sites on plasminogen molecules, hence inhibiting fibrinolysis via its effects on plasmin formation. In a recent large review, the use of TXA and EACA has been found to be effective in reducing blood loss before and after surgery, without serious adverse effects.[64] Hence the use of these agents, as for PCCs, appears to be reasonable in major bleeding, including bleeding attributable to rivaroxaban and dabigatran. Aprotinin, another antifibrinolytic drug, was withdrawn from world markets after serious concerns relating to end-organ damage, including renal failure, myocardial infarction and encephalopathy, but such associations have not been observed with TXA or EACA.

The key pharmacological properties of the new anticoagulants and new antiplatelet agents are briefly described in Table 98.4.

ACQUIRED INHIBITORS OF COAGULATION

Major bleeding can be seen with rare inhibitors of coagulation factors. Autoantibodies against factors VIII (commonest), IX, X, V, and VWF have been reported. Bypassing agents such as rFVIIa and activated prothrombin complex concentrates such as FEIBA (factor VIII inhibitor bypassing activity) have been shown to be efficacious in arresting bleeding in this setting, particularly high-titre inhibitors. The other main aim of treatment is eradication of the offending antibodies. Previously, steroids and cyclophosphamide have been used to achieve this aim. Effectiveness of other treatment approaches, such as immune tolerance regimens and rituximab, has recently emerged. In acute emergencies, particularly in patients with high-titre inhibitors in whom bleeding has not responded to bypass agents, plasmapheresis and immunoadsorption with staphylococcal protein A can be used.

Haematological malignancy

Pascale Gruber and Timothy Wigmore

Haematological malignancies are tumours that involve the bone marrow, blood and lymphoid tissue. They account for 9% of all cancers. The overall prevalence of haematological malignancies is rising, with the greatest increase in non-Hodgkin's lymphoma and multiple myeloma.[1]

Patients with haematological malignancy account for approximately 1.5% of intensive care admissions.[2] They may develop critical illness due to either their underlying cancer or cancer-related treatments such as chemotherapy, radiotherapy or haematopoietic stem cell transplant (HSCT). Some clinical presentations are unique, for example only seen post HSCT, whereas others are more general.

CLASSIFICATION OF HAEMATOLOGICAL MALIGNANCIES

Over the last 30 years, many different classifications have been proposed. Traditional descriptive epidemiology divides haematological malignancies into four broad categories: leukaemia, Hodgkin lymphoma, non-Hodgkin lymphoma and myeloma, with national and international organisations publishing data in this format.[3–5] The revised World Health Organization (WHO) classifies haematological malignancies according to morphology, immunophenotype, genetic and clinical features.[6,7] Myeloid malignancies are categorised into the following groups: myeloproliferative neoplasms, myelodysplastic/myeloproliferative neoplasms, myelodysplastic syndromes, acute myeloid leukaemias, acute leukaemias of ambiguous lineage, precursor lymphoid neoplasms. Lymphoid malignancies are categorised into mature B cell neoplasms, mature T and NK cell neoplasms, Hodgkins lymphoma, histiocytic and dendritic cell neoplasms and post transplantation lymphoproliferative disorders.[8]

LEUKAEMIA

Over 350 000 people are diagnosed with leukaemia each year, worldwide accounting for 2.8% of all cancers.[3] Presenting features include fatigue, lymphadenopathy, hepatosplenomegaly and general symptoms of bone marrow failure such as anaemia, bleeding and reduced resistance to infection. Diagnosis is based on peripheral blood and bone marrow demonstrating blast cells, immunophenotyping, cytogenetic and molecular genetic analysis. The severity of disease, rate of progression and treatment varies greatly between leukaemias, so precise identification of the specific form of leukaemia is crucial to optimum management.

ACUTE MYELOID LEUKAEMIA (AML)

AML is characterised by uncontrolled proliferation of immature myeloid precursor cells. AML rises sharply in middle age and peaks at age 70. The WHO classifies AML into the following subtypes:

- AML with recurrent genetic abnormalities
- AML with myelodysplasia-related features
- Therapy-related myeloid neoplasms
- AML not otherwise specified
- Myeloid proliferations related to Down syndrome
- Blastic plasmacytic dendritic cell neoplasms.

Acute promyelocytic leukaemia (APML) falls within the first subtype. In APML the promyelocytes have dense cytoplasmic granules and Auer rods. The promyelocytes release thromboplastins commonly resulting in disseminated intravascular coagulation. APML responds well to all-trans-retinoic acid (ATRA) treatment.[9,10]

ACUTE LYMPHOBLASTIC LEUKAEMIA (ALL)

ALL is a malignant disorder of lymphoid precursor cells, commonly seen in childhood, with a good overall prognosis. ALL induction chemotherapy typically consists of a 4- or 5-drug regimen of prednisolone, vincristine, anthracycline, L-asparginase and/or cyclophosphamide.[11,12] Patients with ALL frequently have central nervous system involvement, therefore intrathecal chemotherapy or craniospinal irradiation is additionally required. Remission is consolidated with further chemotherapy or HSCT.[10] Prolonged maintenance therapy is often required to eradicate any residual leukaemic cells. A combination of daily methotrexate and 6-mercaptopurine constitutes the basis of most maintenance regimens. Five-year survival is 85–90% for children and less in adults.[13]

CHRONIC LYMPHOCYTIC LEUKAEMIA (CLL)

CLL may be classified as a form of leukaemia or low-grade lymphoma. It is most commonly found in elderly people. Clinical presentation includes fatigue, bone marrow failure, night sweats, lymphadenopathy, painful splenomegaly and autoimmune haemolytic anaemia. The natural history of CLL is variable with a median survival of 8–12 years.[10] Richter's transformation to diffuse large B-cell lymphoma is associated with a poor prognosis (median survival <1 year).[14] First-line treatment is fludarabine, cyclophosphamide and/or rituximab (monoclonal anti-CD20 agent).[15] Alemtuzumab (a monoclonal anti-CD52 agent) is useful in refractory CLL.[16]

CHRONIC MYELOID LEUKAEMIA (CML)

CML is linked to a translocation of chromosomes 22 and 9 (Philadelphia chromosome) leading to formation of BCR-ABL (a tyrosine protein kinase) causing uncontrolled proliferation in mature and immature white cells.[17] CML typically begins in the *chronic phase*, over several years progresses to an *accelerated phase* and eventually results in *blast crisis*. Patients present with weight loss, splenomegaly, fevers and night sweats. Imatinib (a tyrosine kinase inhibitor), a new form of treatment for CML, results in complete remission in approximately 80% of patients avoiding the need for HSCT, which was previously the only curative option for CML.[18]

LYMPHOMA

Lymphomas are tumours of B, T or NK lymphoid cells. Over 420 000 people are diagnosed with lymphoma each year, worldwide accounting for 3.3% of all cancers.[3] Traditionally, lymphomas are divided into Hodgkin's lymphoma and non-Hodgkin's lymphoma (NHL). Lymphomas are staged 1–4 according to lymph node spread and designated A or B depending on the absence or presence of 'B' symptoms: night sweats, fever and weight loss.

HODGKIN'S LYMPHOMA

Hodgkin's lymphoma is common in young people aged between 20 and 30 years. Classic presentation is of cervical lymphadenopathy, fever, night sweats, weight loss and pruritus. Reed–Sternberg cells are characteristic on histology. Choice of combination chemotherapy for Hodgkin's lymphoma depends on the patient's age, sex, tumour size and the histological subtype. Radiotherapy may be given for localised or bulky disease.[19] Combination chemotherapy with or without radiotherapy is curative in 75% of newly diagnosed patients with Hodgkin's disease.[10]

NON-HODGKIN'S LYMPHOMAS (NHL)

NHL is a heterogeneous group of conditions with over 30 subtypes. NHL are broadly divided into high and low grade. High-grade lymphomas tend to be aggressive but chemosensitive, whereas low-grade lymphomas are typically slow-growing, indolent and incurable.[10]

Low-grade lymphomas

Low-grade lymphomas encompass follicular lymphoma (most common), mantle cell lymphoma, marginal zone lymphomas and Waldenstrom macroglobinaemia. The clinical presentation, rate of disease progression and treatment modalities vary widely. The disease may continue for years and treatment is not always indicated.

High-grade lymphomas

The most common high-grade lymphoma is diffuse large B-cell lymphoma (DLBCL), accounting for about 30% of new cases of NHL. It typically affects elderly or middle-aged adults. First-line treatment of early-stage DLBCL includes CHOP chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisolone) with or without involved field radiotherapy.[20] Early-stage DLBCL is potentially curable with a 5-year survival of 70–80%.[21] Burkitt's lymphoma produces fast-growing tumours. There are three distinct variants of Burkitt's lymphoma: (1) endemic (African), (2) sporadic and (3) immunodeficiency associated. These forms differ in their clinical presentation and epidemiology but share the same aggressive nature. Childhood Burkitt's lymphoma is highly responsive to combination chemotherapy with a 5-year survival >90%. Risk of tumour lysis syndrome with Burkitt's lymphoma is high.[22]

MULTIPLE MYELOMA

Multiple myeloma is a plasma cell malignancy that accounts for 0.8% of all cancers and 10% of the haematological malignancies.[3] Patients present with bone pain, fractures and bone marrow failure with associated cytopenias. Renal failure is common due to light chain deposition in renal tubules, amyloidosis and hypercalaemia from bone destruction. Multiple myeloma is not curable but chemotherapy induces temporary remission. Typically, patients experience repeated episodes of relapse, treatment and remission over several years until the disease can no longer be controlled. Overall 5-year survival for multiple myeloma is around 35%. High-dose chemotherapy with HSCT is increasingly being used to reduce symptoms and increase survival.[23]

TREATMENT OF HAEMATOLOGICAL MALIGNANCIES

Haematological malignancies are treated using chemotherapy, radiotherapy or a combination of both with the intent of inducing remission or cure. HSCT offers the only hope of cure in some conditions, but is not without risks.

CHEMOTHERAPY

Chemotherapeutic agents, either individually or in combination, are used to induce cure or remission. Chemotherapeutic agents and regimens commonly used for treatment of haematological malignancies are outlined in **Table 99.1**. The goal of *induction therapy* is to achieve remission by reducing the number of leukaemic cells to an undetectable level; the goal of *consolidation therapy*, which follows induction therapy, is to eliminate any residual undetectable disease and achieve cure. *Maintenance therapy* is frequently used in ALL and APML to prolong remission. Chemotherapy may also be used as part of a conditioning regimen with or without total body irradiation prior to HSCT. Recent advances in the understanding of haematological cancers have led to an increase in the variety of chemotherapy and targeted therapies now available. Administration of some chemotherapeutic agents may result in life-threatening side-effects.

IFSOFAMIDE NEUROTOXICITY

Ifosfamide may be used in the treatment of lymphomas. It causes reversible neuropsychiatric disorders in 10–30% of patients including visual or auditory hallucinations, confusion, personality disorders, anxiety, extrapyramidal symptoms, seizures and coma. Symptoms occur from 2 to 48 hours after infusion and improve 48 hours after discontinuation of the drug. Risk factors include serum albumin <35 mg/dL, hyponatraemia, elevated serum creatinine, previous cisplatin use and bulky abdominal disease. Treatment involves normalisation of serum electrolytes and albumin, benzodiazepines (for seizures) and methylene blue.

RETINOIC ACID SYNDROME

Patients with APML treated with ATRA are at risk of retinoic acid syndrome. The condition is potentially life threatening and the diagnosis is based on the presence of dyspnoea, fever, weight gain, peripheral oedema, shock, acute kidney injury, heart failure, pericardial and pleural effusions. Management involves discontinuation of ATRA and administration of steroids.[9]

RADIOTHERAPY

Radiotherapy can be used alone or in combination with chemotherapy for lymphoma and myeloma. Total body irradiation (TBI) may be instituted as part of the myeloablative regimen in HSCT. Side-effects include gastrointestinal dysfunction, mucositis, pneumonitis, alopecia and skin irritation.

HAEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT)

HSCT has now become the standard treatment for many haematological malignancies because it is potentially curative. Approximately 50 000 to 60 000 patients undergo HSCT per year.[24] Reported rates of ICU admission range from 11 to 20% with higher rates of ICU admission after allogeneic transplant.[25–27] HSCT are divided according to the source of the stem cells (peripheral, bone marrow or umbilical cord) and donor of the cells (autologous or allogeneic). Autologous transplant involves re-infusing harvested peripheral blood taken from the patient during periods of remission after myeloablative conditioning. With autologous transplant patients risk the possibility of re-infusion of the patient's tumour cells and future disease relapse however treatment related mortality is less than 5%.[28,29] Allogeneic transplants involve the infusion of donor cells (sibling or mixed unrelated donor). Immunosuppression is required to reduce the risks of graft-versus-host-disease (GvHD) and graft failure. Treatment related mortality for allogeneic transplants are higher due to the intensive myeloablative regimens and immunosuppression required.

Prior to HSCT patients undergo myeloablative conditioning to destroy endogenous bone marrow cells using radiotherapy and/or chemotherapy. Typical myeloablative regimens include a combination of busulfan, cyclophosphamide and TBI. Reduced-intensity conditioning regimens such as fludarabine and low-dose TBI or fludarabine and busulfan are used for patients who are older, have multiple co-morbidities, or are undergoing repeat transplants. They are less toxic to the bone marrow but are sufficiently immunosuppressive to permit engraftment of donor cells.

CONDITIONS SPECIFIC TO HSCT PATIENTS

Infection

Following HSCT, the immune system takes several weeks to recover; the rapidity of recovery is dependent on the type of transplant, source of stem cells, age of the recipient and donor, conditioning regimen, presence of GvHD and degree of immunosuppression.[30] Most ICU admissions are during the early phase. The period of engraftment is divided into three phases subjecting the transplant recipient to risks of different infections:[31]

1. *Pre-engraftment (<30 days):* the recipient is at risk of bacterial infections due to neutropenia.
2. *Early post-engraftment (30–100 days):* cell-mediated immunity is impaired and the recipient is at risk of viral and fungal infections (cytomegalovirus (CMV), *Pneumocystis jirovecii* and *Aspergillus* spp.).
3. *Late post-engraftment (>100 days):* impaired reticulo-endothelial, cell-mediated and humoral functions mean recipients are at risk of *Mycobacteria* and viruses.

The use of novel broad-spectrum antibiotics with excellent Gram-negative coverage has resulted in Gram-positive organisms (*Staphylococcus* spp., *Streptococcus*, *Enterococcus*) being responsible for the majority of bacteraemias following HSCT.

Table 99.1 Common chemotherapeutic agents used in haematological malignancies[10]

CATEGORY	MODE OF ACTION	CHEMOTHERAPEUTIC AGENTS	SIDE-EFFECTS
Alkylating agents	Cells directly damage DNA by forming covalent bonds	Alkyl sulfonates Busulfan	Pulmonary fibrosis Seizures Thromboembolism
		Mustard gas derivatives Chlorambucil Cyclophosphamide Ifosfamide Melphalan	Haemorrhagic cystitis Neurotoxicity Myelosuppression GI disturbance Hepatotoxicity
		Triazines Dacarbazine Procarbazine	Myelosuppression GI disturbance
Anti-metabolites	Interferes with DNA and RNA growth by acting as inhibitors of enzymes processing purine and pyrimidines	Folic acid antagonist Methotrexate	Pneumonitis Myelosuppression Hepatotoxicity
		Purine antagonist 6-mercaptopurine	Myelosuppression GI disturbance
		Pyrimidine antagonists Capecitabine Cytarabine Gemcitabine	Myelosuppression Pneumonitis Cardiac arrhythmias GI disturbance
		Adenosine deaminase inhibitor Fludarabine	Myelosuppression Autoimmune haemolytic anaemia
Anti-tumour antibiotics	Interfere with enzymes necessary for DNA replication	Anthracyclines Doxorubicin Daunorubicin	Cardiomyopathy
		Miscellaneous Bleomycin	Pulmonary fibrosis
Plant alkaloids	Inhibit mitosis by interfering with the assembly of microtubule structure	Vinca alkaloids Vinblastine Vincristine	Peripheral neuropathy Hyponatraemia Myelosuppression
Topoisomerase II inhibitors	Interferes with enzymes involved in regulating DNA coiling	Etoposide	Myelosuppression GI disturbance Rash
Tyrosine kinase inhibitors	Binds to the site of tyrosine kinase activity, preventing its activity and causing tumour cell apoptosis	Imatinib	Cardiac failure Pneumonitis Rash Fluid retention
Miscellaneous	Ribonucleotide reductase inhibitor	Hydroxyurea	Myelosuppression Hepatotoxic Nephrotoxic Mucositis
	Binds to retinoid-dependent receptors (RAR) involved in cellular growth, proliferation and differentiation	All-trans retinoic acid (ATRA)	Retinoic acid syndrome Headache Hypertriglyceridaemia
	Depletion of cellular asparagine	Asparaginase	Pancreatitis Thromboembolism Myelosuppression

Table 99.1 Common chemotherapeutic agents used in haematological malignancies—cont'd

CATEGORY	MODE OF ACTION	CHEMOTHERAPEUTIC AGENTS	SIDE-EFFECTS
Immunotherapy	Monoclonal antibodies to CD20	Rituximab	Fever Muscle and joint pain Cardiotoxicity Hepatotoxicity Nephrotoxicity
	Monoclonal antibodies to CD52	Alemtuzumab	
	Non-specific immunotherapy	Interferon alpha	
	Immunomodulatory agents	Thalidomide Lenalidomide	Thromboembolism Peripheral neuropathy Thrombocytopenia

NOMENCLATURE OF COMMONLY USED COMBINATION CHEMOTHERAPEUTIC REGIMENS

	CHEMOTHERAPY	HAEMATOLOGICAL MALIGNANCY
FCR	Fludarabine+cyclophosphamide+rituximab	CLL
ABVD	Doxorubicin+bleomycin+vinblastine+dacarbazine	HL
BEACOPP	Bleomycin+etoposide+doxorubicin+cyclophosphamide+vincristine+procarbazine+prednisone	HL
R-CVP	Rituximab+cyclophosphamide+vincristine+prednisone	NHL
R-CHOP	Rituximab+cyclophosphamide+doxorubicin+vincristine+prednisone	NHL
R-FCM	Rituximab+fludarabine+cyclophosphamide+mitoxantrone	NHL
ProMACE-CytaBOM	Prednisone+doxorubicin (Adriamycin)+cyclophosphamide+etoposide+cytarabine+bleomycin+vincristine (Oncovin)+methotrexate+leucovorin	NHL
m-BACOD	Methotrexate+leucovorin+bleomycin+doxorubicin (Adriamycin)+cyclophosphamide+vincristine (Oncovin)+dexamethasone	NHL
MACOP-B	Methotrexate+leucovorin+doxorubicin (Adriamycin)+cyclophosphamide+vincristine (Oncovin)+prednisone+bleomycin	NHL
VAD	Vincristine+doxorubicin (Adriamycin)+dexamethasone	Multiple myeloma

Please note the table above highlights only some of the commonly used regimens. GI disturbance=gastrointestinal disturbance; CLL=chronic lymphocytic leukaemia; HL=Hodgkin's lymphoma; NHL=non-Hodgkin's lymphoma.

CMV infection is a major cause of morbidity and mortality after HSCT. CMV infection may present as a meningitis, colitis, uveitis and pneumonitis. The reported mortality in HSCT patients with CMV pneumonia is 85%.[32] CMV antigen surveillance and use of prophylactic ganciclovir in HSCT recipients who are CMV positive or have received transplants from CMV donors have led to a decrease in CMV infections.[31] Similarly, *P. jirovecii* pneumonia is less common with the effective use of trimethoprim–sulfamethoxazole prophylaxis. Fungal infections continue to be problematic with *Aspergillus* spp. and *Candida* spp. predominating. The routine use of azole prophylaxis has reduced the number of *C. albicans* infections but resulted in the emergence of azole-resistant species.

Graft-versus-host disease (GvHD)

GvHD occurs when the donor marrow recognises the host tissue as foreign and generates an immune response. The incidence of GvHD is 30–50% post-allogeneic transplant and increases with HLA mismatch, advanced age of the donor and recipient, inadequate immunosuppression, intensive myeloablative conditioning and the use of peripheral blood as the stem cell source. Acute GVHD presents with a maculopapular skin rash (especially affecting palms and soles), diarrhoea and intrahepatic cholestasis 7–28 days post-transplant. Acute GVHD is staged and graded according to the number and extent of organ involvement[33] (**Tables 99.2** and **99.3**).

The diagnosis of acute GvHD may be confirmed with a skin, rectal, or liver biopsy. Prophylaxis involves the use of immunosuppressants such as prednisolone, ciclosporin (cyclosporine) and mycophenolate mofetil. Treatment of severe acute GvHD involves high-dose pulsed methylprednisolone and/or additional immunosuppressive agents. Gastrointestinal involvement with secretory diarrhoea may necessitate the need for parenteral nutrition and octreotide. The degree

Table 99.2 Clinical staging of acute GvHD

STAGE	SKIN RASH	LIVER (BILIRUBIN μMOL/L)	GASTROINTESTINAL TRACT (DIARRHOEA IN L/DAY)
1	Maculopapular rash <25% of BSA	35–50	0.5–1
2	Maculopapular rash 25–50% of BSA	51–102	1–1.5
3	Maculopapular rash >50% of BSA	102–225	>1.5
4	Generalised eythroderma with bullae	>225	Severe abdominal pain with or without ileus

BSA=body surface area.

of acute GVHD is predictive of 100-day survival.[34] Chronic GvHD is a multi-organ syndrome which occurs >100 days post-transplant. It can be limited or extensive with skin (itchy dry skin, scleroderma), pulmonary (bronchiolitis obliterans), eye (sicca, keratitis), salivary glands (xerostomia) and neuromuscular (polyneuropathy, polymyositis, myasthenia gravis) involvement and liver dysfunction (hepatitis, cirrhosis). Treatment is often difficult and progression can be limited by increasing the dose of immunosuppression (with a consequent risk of infection).

Graft failure

Graft failure occurs when there is a failure to establish haematological engraftment after HSCT. It occurs in less than 5% of patients following allogeneic HSCT. Causes of graft failure include inadequate stem cell infusion, infection and GvHD. Graft failure is associated with an increased transplant mortality and risk of infection. Management consists of augmentation by granulocyte-colony stimulating factor (G-CSF), infusion of stem cells without additional chemotherapy or a repeat HSCT.

Diffuse alveolar haemorrhage (DAH)

DAH occurs in 5% of HSCT patients. It occurs within 30 days of transplant and is caused by injury to the pulmonary endothelial lining from chemo- and radiotherapy. Age, acute GvHD, intensive pre-transplantation chemotherapy, TBI and allogeneic transplant are important risk factors. Patients typically present with pyrexia, dyspnoea, cough, anaemia and diffuse infiltrates on chest radiographs in the absence of infection. Haemoptysis is rare. Bronchoalveolar lavage (BAL) is bloody and cytology shows haemosiderin-laden macrophages. Treatment is with high-dose steroids and the response is variable.

Idiopathic pneumonia syndrome (IPS)

The incidence of IPS is approximately 7% and it is commonly seen 3 weeks after HSCT. Typical presentation is of diffuse infiltrates on chest radiography or CT scan in the absence of an infective aetiology. Risk factors include allogeneic transplant, GvHD and CMV-positive donor status, pre-transplant radiation, and

Table 99.3 Grading of acute GvHD

GRADE	CLINICAL MANIFESTATIONS
I	Stage 1–2 skin, no gut or liver involvement
II	Stage 3 skin, stage 1 gut or stage 1 liver
III	Stage 3 skin, stage 2–4 gut or stage 2–3 liver
IV	Stage 4 skin, stage 4 gut or liver

chemotherapy (busulfan, cyclophosphamide). Treatment is mainly supportive and, even with aggressive care, the mortality is over 70%.

Engraftment syndrome

Engraftment syndrome (also known as capillary leak syndrome) typically presents 4–5 days after autologous HSCT with fever, erythematous rash and non-cardiogenic pulmonary oedema. Other features include abnormal liver function tests, transient encephalopathy and multi-organ failure. The underlying pathophysiology is related to the release of pro-inflammatory cytokines and neutrophils. Use of G-CSF increases the prevalence of this syndrome and, should it occur, G-CSF must be discontinued. CT scan of the chest typically demonstrates bilateral ground-glass opacification. Management is supportive and steroids may be useful.

Cryptogenic organising pneumonia (COP)

COP, also known as bronchiolitis obliterans organising pneumonia, occurs in 1% of recipients 1–3 months following HSCT and presents with dyspnoea, fever and cough. CT scan of the chest typically demonstrates a ground-glass appearance and lung biopsy shows granulation tissue and fibroblasts in the small airways. Treatment response to steroids is usually good.

Veno-occlusive disease (VOD)

VOD, also known as sinusoidal obstruction syndrome, presents as a triad of painful hepatomegaly, jaundice and ascites 3 weeks following HSCT. Other features include weight gain, encephalopathy, bleeding, and hepato-renal syndrome. The disease spectrum ranges from a mild reversible condition to multi-organ failure.

Risk factors for VOD include myeloablative conditioning (busulphan, cyclophosphamide), pre-existing abnormal liver tests, intra-abdominal radiotherapy and repeat HSCT. The diagnosis is made by hepatic dopplers showing reversed or reduced portal flow of the hepatic vessels. A transjugular liver biopsy may also help establish the diagnosis. Management and prophylaxis in high-risk patients involve the use of defibrotide, a polydeoxyribonucleotide with anti-thrombotic, anti-inflammatory and fibrinolytic effects.[35] Severe VOD has a mortality of 85%.

Posterior reversible encephalopathy syndrome (PRES)

PRES is a syndrome characterised by confusion, headache, visual loss, and seizures commonly associated with HSCT and immunosuppressive agents (e.g. ciclosporin). T_2-weighted MRI characteristically shows diffuse hyperintensity involving the parieto-occipital white matter (**Fig. 99.1**).

The treatment is targeted at the underlying cause.

Post-transplant lymphoproliferative disorder (PTLD)

PTLD is a well-recognised but uncommon complication of allogeneic transplant. It is characterised by uncontrolled proliferation of EBV-infected B cells and results in impairment of T-cell immunity. Risks factors include previous EBV donor or recipient exposure, aggressive immunosuppression and T-cell-depleted transplants. EBV viral load should be monitored regularly on serial blood samples. Treatment involves reduction or withdrawal of immunosuppression with the potential risk of GvHD. Intravenous immunoglobulin, anti-B-cell monoclonal antibodies, rituximab and infusion of donor T cells have all been used with variable success.

Thrombotic thrombocytopenic purpura (TTP)

Secondary TTP following HSCT is thought to be due to chemotherapy-induced endothelial damage. Classic presentation is of renal failure, fever, thrombocytopenia, fluctuating neurological signs (confusion, mood changes, seizures and drowsiness) and microangiopathic haemolytic anaemia. The blood film typically shows red cell fragments and the haemolysis screen is positive. Treatment is supportive and involves plasmapheresis, broad-spectrum antibiotics and high-dose steroids. Haemolytic uraemic syndrome is a similar entity and may be distinguished from TTP by the lack of neurological signs and fever.

ACUTE ONCOLOGICAL EMERGENCIES

ACUTE ONCOLOGICAL EMERGENCIES REQUIRING URGENT CHEMOTHERAPY OR RADIOTHERAPY

A small number of patients are admitted directly to ICU with complications of their haematological malignancy requiring urgent chemotherapy and/or radiotherapy. These include:

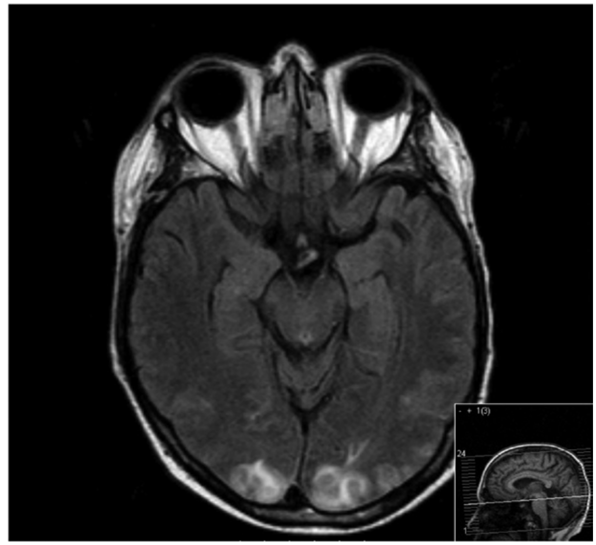

Figure 99.1 MRI scan of posterior reversible encephalopathy syndrome, showing the characteristic diffuse hyperintensity.

1. *CNS involvement:* CNS involvement resulting in focal deficits, seizures, alteration of consciousness or high spinal cord compression is an indication for urgent chemotherapy and/or radiotherapy.
2. *Mediastinal masses and pericardial disease:* bulky mediastinal masses with compression of trachea, main bronchi or major vessels are often due to NHLs and require urgent chemotherapy and/or radiotherapy to relieve the compression (**Fig. 99.2**).
3. *Disseminated intravascular coagulation (DIC):* DIC may be a presenting feature of APML. Specific chemotherapy such as ATRA and supportive measures such as regular platelet transfusions and fresh frozen plasma reduce the risk of bleeding. Use of low-dose unfractionated heparin is not recommended as routine practice.
4. *Hyperviscosity syndromes:* hyperviscosity syndromes occur with multiple myeloma, leukaemia and Waldenstrom's macroglobinaemia. Clinical manifestations include headaches, coma, seizures, visual impairment, retinal haemorrhages, and bleeding. Emergency management is directed at decreasing blood viscosity by plasmapheresis followed by urgent chemotherapy aimed at reducing monoclonal immunoglobulins.
5. *Macrophage activation syndrome (MAS):* MAS, also known as haemophagocytic lymphohistiocytosis, is a recognised presentation of NHL and HD. Typical manifestations of MAS are fever, hepatosplenomegaly and thrombocytopenia. Vasodilatory shock, acute respiratory distress syndrome and acute kidney injury may also occur. Laboratory findings include low erythrocyte and leucocyte counts,

Figure 99.2 A mediastinal mass.

hypoalbuminaemia, hypertriglyceridaemia, hypofibrinogenaemia, hyperferritinaemia (>500 µg/L). Bone marrow findings show activated macrophages phagocytosing platelets, erythrocytes and leucocytes. Steroids and etoposide are the mainstays of treatment.

6. *Leukostasis:* Leukostasis is defined as a total leucocyte count of $>100 \times 10^9$/L. It is seen in patients with AML or AML in blast crisis. White cell plugs in the vasculature cause decrease tissue perfusion and result in neurological dysfunction and respiratory failure.[36] Leukostasis is associated with a high mortality and prompt treatment with chemotherapy and leukapheresis is indicated.

In some circumstances starting chemotherapy in the ICU, even when infection or organ failure is present, may be appropriate to limit disease progression that may result in death. Modification of chemotherapeutic regimens may be required to limit organ toxicity and the duration of neutropenia. In carefully selected cases of patients given chemotherapy in the ICU, published outcomes have been reasonable with an in-hospital mortality of 43%.[37] In fact, the administration of chemotherapy, in the ICU setting or within the last 3 weeks prior to ICU admission, does not appear to be associated with an increased risk of death.[38]

NEUTROPENIA AND NEUTROPENIC SEPSIS

Neutropenia is defined as an absolute neutrophil count (ANC) of $\leq 0.5 \times 10^9$/L. Fever is common in patients with haematological malignancies and differentiating infectious from non-infectious causes of fever is notoriously difficult. Assessment relies on the early identification of a likely source, microbiological surveillance and surrogate information from biomarkers. Severe sepsis and septic shock in patients with haematological malignancies has a reported mortality of 36–45%.[39,40] High-risk patients are those with significant co-morbidities and prolonged (>7 days) and profound neutropenia. Neutropenic sepsis is potentially fatal if left untreated.[41] Patients with neutropenic sepsis and evidence of organ failure must have antibiotics administered within 1 hour of presentation. A minimum of two sets of blood cultures should be collected: with a set collected from each lumen of a vascular access device, if present, and from a peripheral vein site; 2 blood culture sets from separate venepunctures should be sent if no central venous catheter is present. A chest radiograph and culture specimens from other sites of suspected infection (sputum, stool, urine) should also be taken. The Infectious Diseases Society of America recommends first-line antimicrobial treatment with an anti-pseudomonal beta-lactam agent, such as cefepime, a carbapenem (meropenem or imipenem–cilastatin), or piperacillin–tazobactam. Aminoglycosides, fluoroquinolones, and/or vancomycin should be added to the initial regimen in the event of septic shock or if antimicrobial resistance is suspected.[42] Vancomycin (or another agent active against Gram-positive cocci) should also be added if there is a suspected catheter-related infection, skin or soft-tissue infection or pneumonia. In intensive care units where there is a high incidence of multiresistant organisms, it may be necessary to use a second-line agent such as linezolid. Empirical antifungal therapy should be considered for patients with persistent or recurrent fever after 4–7 days of antibiotics. The need for antiviral agents or trimethoprim–sulfamethoxazole should be evaluated on an individual patient basis. G-CSF is often used to promote neutrophil recovery in patients with profound neutropenia. Blood cell counts should be obtained daily, and the G-CSF should be discontinued when the neutrophil count is $\geq 1.0 \times 10^9$/L. Side-effects of G-CSF include rash, injection site reactions, bone pain, flu-like symptoms and rarely splenic rupture. Finally, environmental precautions should be taken when managing febrile neutropenic patients with meticulous hand hygiene, full barrier precautions (gloves, gowns, and in some cases overshoes and masks) and patients should be kept in protective isolation. In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) has provided comprehensive guidance on the management of neutropenic sepsis following the National Confidential Enquiry into Patient Outcome and Death (NCEPOD) report (Systemic Anti-Cancer Therapy: For better, for worse? 2008).[43,44]

NEUTROPENIC ENTEROCOLITIS

Neutropenic enterocolitis is also known as typhlitis. Patients typically present with abdominal pain, fever, and diarrhoea after chemotherapy (especially cytosine arabinoside, vinca alkaloids, and doxorubicin). It is caused by a combination of chemotherapy-induced

colonic mucosal wall damage, thrombocytopenia-related gastrointestinal bleeding, and colonisation of the bowel by pathogenic bacteria. Complications include bacteraemia, gastrointestinal bleeding, and perforation (5–10%). Abdominal CT scanning may demonstrate pneumoperitoneum or colonic pneumatosis indicating colonic damage with imminent perforation. Bowel-wall thickening on ultrasound scanning may also help confirm the diagnosis. Management is conservative with bowel rest, parenteral nutrition and antimicrobial therapy that target enteric Gram-negative and anaerobic organisms, including *Clostridium difficile*. Surgery may be required in patients with uncontrolled sepsis, bowel perforation or life-threatening gastrointestinal bleeding.

RESPIRATORY FAILURE

Acute respiratory failure is the most common cause of ICU admission in patients with haematological malignancies. The reason for respiratory failure is often infection, although other non-infectious causes including non-cardiogenic pulmonary oedema, acute respiratory distress syndrome, GvHD, diffuse alveolar haemorrhage, idiopathic pneumonia syndrome, chemotherapy (methotrexate, bleomycin, fludarabine, gemcitabine), cryptogenic organising pneumonia, and tumour infiltration of the lung should be considered (**Table 99.4**). Invasive mechanical ventilation is a poor prognostic indicator.[25,45] Reported mortality for patients who are invasively ventilated following HSCT is 52–96%.[46] Lung-protective ventilation strategies, use of non-invasive ventilation and use of bronchoalveolar lavage (BAL) to aid diagnosis have all contributed to improvements in outcome.[47,48] The diagnostic yield of BAL is 45% and leads to modification in treatment in up to two-thirds of patients but the procedure may precipitate the need for invasive mechanical ventilation. Routine transbronchial biopsy is not recommended as it rarely provides additional useful information but increases the risk of complications.

ACUTE KIDNEY INJURY

Acute kidney injury may be a result of the underlying cancer (monoclonal light chain deposition in multiple myeloma), tumour lysis syndrome, administration of nephrotoxic agents (amphotericin B, foscarnet, aminoglycosides, methotrexate, platin derivatives, cyclophosphamide, ciclosporin), hepato-renal syndrome from veno-occlusive disease, or sepsis. In some cases renal replacement therapy may be required. Studies have shown that the need for renal replacement therapy is an independent predictor of mortality in patients with haematological malignancy.[49,50]

TUMOUR LYSIS SYNDROME

Tumour lysis syndrome is caused by rapid lysis of tumour cells following chemotherapy leading to release of excessive quantities of intracellular contents into the systemic circulation. The metabolic disturbance is characterised by hyperkalaemia, hyperphosphataemia, hypocalcaemia and hyperuricaemia, which may lead to acute kidney injury and cardiac arrhythmias. It is commonly associated with the acute leukaemias and high-grade lymphomas (e.g., Burkitt's lymphoma). Close monitoring of renal function, potassium, calcium, phosphate, and urate levels is required in patients with high tumour burden after starting chemotherapy. Allopurinol or rasburicase (a recombinant urate oxidase enzyme) are used as prophylaxis.[51] Treatment includes aggressive fluid hydration, rasburicase and occasionally renal replacement therapy.

NEUROLOGICAL DYSFUNCTION

Neurological dysfunction may have a number of aetiologies including infection (bacterial, viral or fungal), bleeding, tumour infiltration, hyperviscosity syndromes (multiple myeloma, Waldenstrom haemoglobinaemia), cerebral infarcts, and cerebral venous thrombosis. Some chemotherapy and immunosuppressive agents (methotrexate, cytarabine, 5-fluorouracil, ciclosporin) may present with CNS toxicity and cerebellar syndromes. High-dose cisplatin can cause encephalopathy and optic nerve damage.

GASTROINTESTINAL AND LIVER DYSFUNCTION

Gastrointestinal and liver dysfunction may be associated with chemotherapy (ciclosporin, methotrexate, platinum derivatives), acute GvHD, infection (CMV, EBV, hepatitis, adenovirus, rotavirus, *Clostridium difficile*), veno-occlusive disease and tumour infiltration.

CARDIAC COMPLICATIONS

Cardiac complications such as cardiac failure, arrhythmias, pericardial effusion, myocarditis or endocarditis may be the result of the underlying cancer, chemotherapy (anthracyclines, cyclophosphamide, cisplatin) or infections (EBV, CMV, *Staphylococcus aureus*, *Aspergillus* spp., *Candida* spp.).

PREDICTORS OF MORTALITY IN PATIENTS WITH HAEMATOLOGICAL CANCER

Several studies have looked at predictors of mortality to help identify those patients with haematological malignancy most likely to benefit from ICU care. Some predictors have changed with time such as neutropenia, autologous transplant and underlying haematological diagnosis which are no longer indicative of poor outcome.[52–54] Advanced age, multi-organ failure, mechanical ventilation, vasopressor use, GvHD, elevated serum lactate on admission, allogeneic transplants continue to be associated with poor outcomes.[2,27,45,25,55] Acute Physiology and Chronic Health Evaluation (APACHE) II scores and Simplified Acute Physiology Score (SAPS) II scores often underestimate mortality.[26,56]

Table 99.4 Causes of respiratory failure in a patient with haematological malignancy

CAUSES	EXAMPLES	
Non-infectious	General	Acute respiratory distress syndrome Aspiration pneumonia Cryptogenic organising pneumonia Pulmonary leukaemic infiltration Tumour causing upper or lower airway obstruction Non-cardiogenic pulmonary oedema Chemotherapy-induced pulmonary toxicity Pulmonary interstitial fibrosis
	Specific to HSCT	Diffuse alveolar haemorrhage syndrome Idiopathic pneumonia syndrome Engraftment syndrome
Infectious	Bacterial	*Pseudomonas*, *Klebsiella*, *Acinetobacter*, *Staphylococcus*, *Enterococcus*, *Streptococcus*, *Legionella*, *Mycoplasma*
	Viral	Influenza, parainfluenza, adenovirus, respiratory syncytial virus, cytomegalovirus, herpes simplex virus, varicella zoster virus
	Fungal	*Candida* spp., *Aspergillus* spp., *Pneumocystis jirovecii*
	Mycobacteria	*Mycobacterium* tuberculosis

HSCT=haematopoietic stem cell transplant.

OUTCOMES OF PATIENTS WITH HAEMATOLOGICAL MALIGNANCY ADMITTED TO THE ICU

Previous studies have reported that patients with haematological malignancies who require intensive care often face a poor prognosis with in-hospital mortality rates of >80% reported in the mid-1990s. However, more recent reports have demonstrated better survival. The largest case series to date has demonstrated an in-hospital mortality of 59%.[2] This reduction in mortality is attributed to improvements in chemotherapeutic regimens, better patient selection, targeted therapies with less organ toxicity, appropriately tailored reduced intensity conditioning regimens for HSCT patients and improved ICU care.[57] This trend towards lower mortality also provides a strong argument against the traditionally held negative perception of patients with haematological malignancy admitted to the ICU.

Organ donation

Stephen J Streat

Transplantation of organs and tissues is an established effective treatment for end-stage organ failure and other conditions.[1,2] Demand for transplantation is increasing as recipient outcomes continue to improve. However, organ donation from deceased donors has not correspondingly increased, leading to strident calls for 'solutions to the organ shortage crisis'.[3] Transplant numbers have been maintained or modestly increased by a number of strategies[3] including donation after cardiac death (DCD, formerly called non-heart-beating donation), live donors and varieties of chains of kidney exchange (including altruistic donors, paired and more complex kidney exchange[4]), the use of split livers for two recipients,[3] accepting more organs at higher risk of failure[1] and transplanting two such kidneys into one recipient.[5] Despite professional condemnation of the practice[6] desperate recipients from wealthy countries continue to take part in 'transplant tourism'[7–9] in poorer countries. Concerns have been expressed about internet-facilitated altruistic but directed live donation being potentially vulnerable to commercial exploitation.[10,11] Slow progress continues in alternative approaches to end-stage organ failure, including artificial organs, xenotransplantation and the engineering of organs (and tissues) from stem cells, but no such organ replacement is yet available for clinical use.

Over the last decade in particular there have been marked demographic changes in deceased donors, with no change or a fall in (younger) donors after traumatic brain injury and an increase in (older) donors following cerebrovascular accident, hypoxic–ischaemic encephalopathy and other non-traumatic conditions. Underlying these demographic changes are the combined effects of primary prevention of traumatic brain injury, better treatment of this and other intracranial catastrophes (subarachnoid and intracerebral haemorrhage in particular), changes in intensive care practice and changes in donor acceptability to transplant services. The true incidence of brain death in intensive care settings is largely unreported, in part owing to inconsistent clinical practice with respect to the determination of brain death in patients with apparent loss of brainstem function.[12] In many countries the number of organ donors after brain death is not rising and increases in the number of organ donors have come from DCD.[13,14]

Decompressive craniectomy does not improve long-term outcome after (at least diffuse[15]) traumatic brain injury, but it does control refractory intracranial hypertension,[15] and may thereby reduce the incidence of brain death. Institution of mechanical ventilatory support in poor-prognosis patients with apparent stroke (to facilitate CT scanning) has probably led to more such patients being admitted to ICU, sometimes after family discussion about possible future organ donation. The effectiveness of induced hypothermia for hypoxic–ischaemic encephalopathy after 'shockable' cardiac arrest[16] has led some to suggest its use after resuscitation from 'non-shockable' rhythms[17] where robust evidence of efficacy is absent.[18] Nevertheless this may have led to an increase in the number of poor-prognosis patients admitted to ICU (and cooled) with hypoxic–ischaemic encephalopathy.

RESPONSIBILITIES OF THE INTENSIVIST

Most intensivists support deceased-donor organ donation.[19,20] Those few who do not should make arrangements with other intensivist colleagues for the care of potential organ donors and discussions with their families.[21] Intensivists' responsibilities include the care of dying patients and of their families in the intensive care unit (ICU) – where donation occurs. Increasingly other agencies are defining best organ donation practice (and its language and metrics) in utilitarian ways[22] – e.g. 'transforming the greatest possible number of existing cadavers, in any centre, region or country, into real donors'[23] perhaps because intensive care organisations have largely failed to define what constitutes best practice in organ donation and to take responsibility for ensuring that it takes place. Increasingly, the family discussion of organ donation is being strategically planned, including the involvement of 'trained or designated requestors', and framed in ways which encourage, expect or 'nudge' the family to donate while seeking to overcome what are described as 'barriers or objections' to donation.

Regardless of the personnel involved in organ donation processes, intensivists should surely ensure that the processes involved in deceased-donor organ donation, including DCD, are of the highest standard and continue to be seen as such.[21] These processes

include the care of the dying patient and their family, determination of death, identification of the potential for organ donation to occur, discussing organ donation with the family, maintenance of physiological stability after brain death throughout the time until organ retrieval, withdrawal of treatment and determination of death in DCD, and aftercare for the family of the deceased irrespective of whether organ donation took place.[21]

CARE OF THE DYING PATIENT AND THEIR FAMILY

Intensivists are familiar with the care of the dying patient, including the need to avoid suffering and maintain patient dignity. The respect of the ICU staff for the humanity of the dying person is expressed in the 'patient comfort care' provided by the nursing staff, the continued involvement and attentiveness of the medical staff, and in evident compassion of all staff for the family.[24]

On behalf of all the treating team, an intensivist should establish rapport during an early meeting (e.g. the morning after admission) with the family of every intensive care patient. This is particularly important for families of patients at high risk of death or disability with whom there will often need to be several 'bad news' meetings over several days. Family meetings should be attended by whomsoever the family defines itself to include, by the intensivist, and by a member of the nursing staff supporting the family (preferably the 'bedside nurse' looking after the patient). If the family wishes, the meeting might include a chaplain, social worker or cultural health worker. The 'support' role should be kept separate from the 'bearer of bad news' role. Family meetings should be held in a separate private room large enough to accommodate all the participants, away from the bedside and protected from interruption. The intensivist should convey an accurate account of the sequence of events, a realistic prognosis (in as much as this is possible) and the immediate treatment plan. There must be enough time for family members to speak[25] for discussion and to ensure that any questions that the family may have are answered. At the end of the meeting the intensivist should ascertain that the family understands what has been said[24] and agrees with the immediate plan. Ensuring that all team members give the family congruent messages is an essential part of maintaining the trust of the family in the ICU team. Ideally, one intensivist should speak with the family but where this is impractical it is vital that there be detailed and explicit discussions between one intensivist and another before the next family meeting. A relationship of mutual understanding and trust will enable the ICU team and the family to work together through difficult and painful issues, including withdrawal of intensive therapies,[26] death of the patient and consideration of organ donation.

Many patients who develop apparent loss of brainstem function do so during a period of active surgical and medical treatment. In these circumstances, brain-oriented intensive therapies (including sedatives, opioids, neuromuscular blockers, hypothermia and osmotherapy) should be withheld pending formal assessment of brain death. In order to meet the preconditions for brain death assessment,[21] extracranial physiological stability must be maintained, and these conditions also preserve the future possibility of organ donation.

Withdrawal of intensive therapies is common practice in ICUs worldwide.[26–28] Before recommending withdrawal of therapy in the setting of severe brain damage it is essential to establish prognosis, to the best extent that this is possible. An unconfounded clinical assessment of CNS function, imaging (usually CT but increasingly supplemented by MRI in some conditions – e.g. diffuse axonal injury) and neurophysiology (in particular short-latency somatosensory evoked potentials) all provide important information. During the period of sedative-free CNS assessment, some patients lose apparent brainstem function. If brain death does not occur but devastating brain damage has clearly occurred, those treating the patient (e.g. intensivists, neurosurgeons and others) should achieve a consensus view of prognosis and a recommended treatment plan, which might include withdrawal of intensive treatments (e.g. artificial airway, ventilatory or inotropic support, further neurosurgery). The intensivist should then discuss the prognosis and a recommended plan with the family and facilitate a consensus. Withdrawal of treatment may subsequently occur, either because death is seen to be imminent and inevitable or because the likely survival outcome would not be in accord with the patient's previously expressed wishes or inferred best interests. It is appropriate to withdraw all intensive therapies from such patients, while continuing to provide 'comfort care' to the patient and support to the family.[29] The possibility of future organ donation must have no influence on a decision to limit or withdraw specific brain-oriented therapies. Some patients having intensive treatments withdrawn will die within a timeframe (e.g. 1–2 hours) that makes DCD a possibility. Prediction of early death after withdrawal of therapy (including extubation) is imprecise but such patients usually have deep coma and impaired brainstem function.[30,31] In these situations it is appropriate to discuss DCD with the patient's family. However, the possibility of DCD must not be raised by the treating team before the family and the treating team have reached a consensus that treatment will be withdrawn.

Increasingly families of dying patients volunteer that they (or the patient) would wish for organ donation to take place, if possible. These views are commonly expressed before the determination of brain death in patients who seem very likely to become or may already

be brain dead, but sometimes when the patient still has brainstem function and even prior to a decision that intensive treatments will be withdrawn. The intensivist should sensitively acknowledge these statements and assure the family that this issue will be addressed, without further family prompting, if and when clinical circumstances are appropriate.[21]

IDENTIFICATION OF THE POTENTIAL FOR ORGAN DONATION TO OCCUR

Most ICUs admit ventilated patients with very severe brain damage whose probability of recovery is low. The rationale for this practice is to identify any (small) subgroup of patients with reversible conditions and provide them with the necessary treatment to facilitate their recovery. There are, however, more extreme situations when the chance of recovery is thought so remote that either investigation (CT scanning, usually following intubation and ventilation), active treatment (osmotherapy and emergency surgery) or admission of the patient to ICU[32] would not usually occur.

Some ICUs now routinely admit these patients, either with the rationale that providing them (and their family) with good end-of-life care in an emergency department is not readily achievable, or solely for the possibility that organ donation might subsequently occur. Routinely admitting these patients to ICU has been called for[33] and could probably be expected to increase the number of organs available for transplant,[34] but various ethical, legal and clinical concerns have been raised about such practice.[35–38] Some have suggested that ICU admission should be 'automatic' (without prior family discussion) for these patients while some intensivists admit these patients subject to the informed consent of the family – including an understanding that possible future organ donation is the only reason to admit the patient to ICU, that organ donation might not be possible, and that they are prepared to consider organ donation in the near future should clinical circumstances permit it.

Organ donation is possible in most situations where brain death has been confirmed or when death occurs soon after withdrawal of treatment. The rare absolute contraindications to organ donation are when there is an unacceptably high risk of transmission of disease (usually malignancy or infection) to the recipient, or when the long-term function of all possible donor organs is likely to be unacceptably poor.

Tissue donation (including eyes for corneas and sclera, heart valves and vascular tissue, skin and bone) is also frequently possible in most patients dying in ICUs, including from those who cannot donate organs. Because of the relative benefits and risks to recipients of donated organs and tissues, tissue donation may not be possible in some circumstances where organ donation is acceptable (e.g. low-risk possible food exposure to variant CJD).

Advanced age, most treated bacterial sepsis, treated HSV encephalitis, positive HCV or HBV serology, and some 'apparently cured' malignancies are no longer absolute contraindications. Most extracerebral malignancies and certain infections (e.g. HIV) are likely to remain so, although organs from HIV-positive donors have recently been transplanted into HIV-positive recipients with acceptable outcomes.[39] Similarly, organ-specific relative contraindications to organ donation have reduced as the outcomes of recipients transplanted with donor organs formerly rejected have been found to be acceptable. Finally, all contraindications vary somewhat between transplant centres and continue to change in a more permissive direction. Intensivists should discuss possible absolute and organ-specific contraindications to donation and subsequent transplantation with the appropriate organ donation or procurement agency (who will liaise with transplant services as required) and not decide independently that donation in general or donation of any particular organ is contraindicated on medical grounds. The intensivist should ensure that the information necessary for these decisions is provided (**Box 100.1**).

In most jurisdictions an appropriate authority (e.g. a coroner or medical examiner) may legally interdict organ donation under certain circumstances (e.g. homicide) and this issue must also be clarified before donation proceeds.

DETERMINATION OF BRAIN DEATH

This is a clinical responsibility of the intensivist and must be carried out according to appropriate codes of practice. Although there are no universal criteria for the determination of brain death, codes of practice around

Box 100.1 Information likely to be required by transplant teams

- Age, sex, weight, approximate height
- Medical and social history (including co-morbidity, surgery, medication, alcohol, smoking, illicit drug use, tattoos, body piercing, sexual history and allergies)
- Detailed clinical history of fatal illness (including cause of death, history of cardiac arrest, periods of hypotension or hypoxia, evidence of aspiration or sepsis)
- Current clinical status (including physiological parameters and the extent of ventilatory and inotropic support)
- Current investigations (including blood group, arterial blood gases, chest X-ray, ECG, serum urea, creatinine, electrolytes, glucose, bilirubin, transaminases, alkaline phosphatase and γ-glutamyl transpeptidase, prothrombin ratio, activated partial thromboplastin time, haemoglobin, white cell count, platelets and all microbiology results)
- Other investigations may sometimes be required (e.g. echocardiogram, coronary arteriogram, bronchoscopy)

the world are very similar and all require[21,40,41] (at least) these three elements:

1. Establishing the presence of a condition known to produce severe and irreversible structural brain damage
2. Exclusion of possible confounding factors
3. Determination by clinical examinations (usually by two independent doctors) that there is profound unresponsive coma and persistent absence of brainstem function.

The clinical examination for the determination of brain death is facilitated by a proforma (e.g. the ANZICS protocol[42]), which should be included in the medical record. When clinical examination is not possible (e.g. when it is confounded by medications or when brainstem reflexes cannot be examined), then the absence of cerebral blood flow must instead be demonstrated by reliable imaging.[21]

The intensivist should convey the fact of brain death and its medical and legal implications to the family. It can be difficult to accept brain death as death, given the life-like appearance of the skin, the rise and fall of the chest and the warmth of the hands that are preserved by ventilatory and circulatory support. Some family members will accept an offer to view the clinical examination for brain death (with prior careful explanation of the possibility of spinal reflexes), or the cerebral blood flow study when clinical examination is confounded. This may help some to understand and accept the final awful implication of this diagnosis. Intensivists should be open to offering these options. In the absence of organ donation, it is appropriate to remove ventilatory support after brain death when family needs have been met.

DONATION AFTER CARDIAC DEATH

Donation after cardiac death (DCD), previously known as non-heart-beating donation, is increasing around the world but is not yet worldwide practice. Kootstra and colleagues from Maastricht[43] described four categories of 'non-heart-beating' donors and this classification remains in common use.

- *category I:* those who are dead on arrival
- *category II:* those in whom cardiopulmonary resuscitation is ceased
- *category III:* those in whom cardiac arrest is expect to soon occur
- *category IV:* those who have cardiac arrest while brain dead.

In all but Category III the situation is 'uncontrolled'.[43] DCD practice varies considerably worldwide. Category II donors are most common in the Dutch experience but donation does occur from all categories. Almost all DCD donors in the UK, USA, Canada and Australasia are Category III (and a small number are Category IV). By contrast, in Spain, although withdrawal of treatment in ICU is far less common than in Holland or the UK[44] and Category III donors are rare, most DCD donors are Categories I and II.[45] Recently DCD after euthanasia has been reported, so far only from Belgium.[46]

It is at times asserted about DCD that 'all organ donation occurred this way' before brain death was legally accepted as death, but this assertion ignores real differences between DCD in the modern era and historical organ removal after brain death in the past. The syndrome of brain death had been recognised many years before deceased donation; for example, absent cerebral blood flow was reported in 1956[47] and the clinical syndrome in 1959.[48,49] The final awful meaning of the brain death syndrome ('apnoea, fixed dilated pupils, polyuria, hyperglycaemia and spontaneous hypothermia')[50] was understood by intensivists and nephrologists in the 1960s and 1970s and conveyed to families at that time, before there was a discussion of organ donation (PB Doak, RV Trubuhovich, personal communications). Organ donation was not discussed with the family if some brainstem function (usually only a tracheal reflex) was known to be present. Apnoea despite hypercarbia was not specifically tested for but the shared expectation of the family and the treating team was that the patient would not breathe after withdrawal of ventilatory support (although in fact a few did, for a short time and inadequately). Cardiac arrest usually occurred in 15–20 minutes, at which point the patient was determined to be dead and the kidneys were removed.

There are differences between organ donation after brain death (DBD) and (Category III) DCD that have ethical and clinical consequences. These include that in DCD the patient is known to be alive, and not to be (brain) dead, at the time that organ donation is discussed, may well breathe after extubation and may not die within the timeframe in which organ donation is possible.

The legal, ethical and medical issues raised by DCD have been widely explored.[21,43,51–55] These include ensuring that there has been a consensus decision to withdraw treatment before organ donation is discussed with the family, estimating the likelihood of death soon after withdrawal of treatment, use of agents (e.g. heparin) and procedures (e.g. instrumentation) prior to death that are for 'organ benefit only', the location of withdrawal of treatment (ICU, operating room or other location), presence of family members after withdrawal of treatment, use of opioids and sedatives after withdrawal of treatment, separation of clinical responsibility for end-of-life care (including opioids, sedatives and determination of death) from responsibility for organ procurement, the exact method used for determination of death, the timing of organ removal after death, the procedure to be followed if the patient does not die within a timeframe where donation is possible, ensuring that the family are fully informed and supported

throughout the process, ensuring that all participating personnel are familiar with, and accepting of, DCD procedures and ensuring that agreed protocols that explicitly address all of these issues are in place. Several national guidelines or recommendations have been produced that address these issues.[21,54–56] DCD should take place only after broad clinical, ethical and societal consensus has been achieved and expressed in such a document. Where such a measured process has been followed, DCD has been viewed favourably by both families and hospital staff and has modestly increased the number of organs available for transplant.

Delayed graft function is more common in recipients of DCD kidney grafts, but long-term recipient outcomes are equivalent to those who receive a graft from a brain-dead donor.[57] Lower graft and patient survival with DCD liver grafts, compared with DBD grafts, is commonly reported (e.g. 5-year graft survival 52% vs 66%, 5-year patient survival 65% vs 72%),[58] but equivalent outcomes (e.g. 5-year graft survival 83% vs 81%, 5-year patient survival 88% vs 85%)[13] have been achieved where DCD grafts have been used more cautiously. Recipient and graft outcomes after pancreas[59] and lung transplantation[60] from DCD donors are similar to those after DBD. Although successful heart transplantation from DCD donors has been reported, experience is insufficient so far to characterise the long-term recipient outcomes.

DISCUSSION OF ORGAN DONATION WITH THE FAMILY

Organ donation (from deceased donors) is an activity that takes place at the end of life, usually in an ICU. Organ donation is quite separate from transplantation, which is concerned with the care of patients with end-stage organ failure who may receive organ transplants. Appreciating this distinction enables an understanding of important issues that are not often discussed in transplant-oriented publications. Organ donation fundamentally modifies human rituals at the time of death, even of death in the ICU. Organ removal is an invasive procedure carried out in the operating room. Although done respectfully and with identical surgical processes to those used on living people, it is nevertheless viewed by some as 'mutilating'. Discussion of organ donation is an emotionally intense activity involving a newly bereaved family and a health professional, and requires very clear and sensitive communication. This discussion takes place in the midst of grief – when family members are experiencing the death of a family member. Awareness of transplantation varies widely in the community and there is even less knowledge of organ donation processes. Some families may not previously have known that organ donation and transplantation occur! Similarly, discussion of and support for organ donation vary widely in the community. There is greater support of 'organ donation in principle' than either individual willingness to donate or willingness to agree to donation on behalf of a family member. Discussion of organ donation among families is promoted as a way of increasing organ donation rates and it may do so. However, some family members hold strong views against organ donation based on spiritual, religious or cultural beliefs.[61] There are utilitarian views about organ donation including the notion that organ donation is the only possible positive outcome that can occur in the setting of brain death,[62] that it is appropriate to refer to dead or dying persons in a utilitarian way as sources of organs for transplant,[63] that organ donation can 'help the next of kin cope with grief',[64] and that fulfilling the previously expressed wishes of the donor should be the primary or indeed the only[65] consideration. In some jurisdictions these wishes have been deemed legally sufficient for organs to be retrieved, and are often assumed to be a means of increasing the organ donation rate[66] by excluding the family from the opportunity to prohibit organ donation and 'returning control to the individual'. This assumption may well be erroneous.[67,68] Many countries have defined the status of an individual's wishes about organ donation after their death as constituting legally sufficient 'consent'. However, the validity of the concept of 'consent' can be questioned as the person is dead at the time that the issue is real and because it is unlikely that current 'register-based' records of such wishes meet accepted standards for informed consent[69] in a personal healthcare context.[70] Implicit in a 'transplant-oriented' value system is the view that for a family to agree to organ donation is both desirable and of greater moral value ('the right thing to do') than the contrary decision, particularly if organ donation was the previously expressed wish of the dead person. This view, in which close family relationships[71] give no legitimacy to the family to determine what should happen to their loved one after death, is now explicitly acknowledged, practised and advocated by many USA organ procurement organisations (e.g. S Gunderson, personal communication). Similar views are increasingly expressed in the UK and Australia. Even in countries that legally allow the previously expressed wishes of the deceased to determine whether organ donation may take place, usual practice continues to both involve the family and not to proceed against family objection – accepting that the impact on the deceased's family is the most important factor determining consent practice.[72] However, in many countries this has resulted in the evolution, exposition and advocacy of strategies to overcome 'refusal to donate'[73] and to thereby achieve 'target conversion rates'. Possible adverse effects of such strategies on family bereavement[74] are not reported by those who advocate for them and whose sole measure of 'quality' or 'success' in organ donation practice is the proportion of situations in which donation occurs. Intensivists should reflect on their own views on these matters, and be aware of the views of

others who might discuss organ donation with family members.

Although intensivists most often initiate discussion of organ donation with families in Australasia, this is increasingly unusual elsewhere. Whoever undertakes this discussion should be skilled in communication with grieving people. In Australasian clinical practice, the intensivist has already established a relationship with the family, involving mutual trust and respect, in prior family meetings during the patient's final illness. This relationship naturally allows the intensivist to initiate and facilitate discussion of organ donation. Describing this encounter as 'discussing organ donation' rather than 'obtaining consent' (or 'seeking consent' or even 'persuasion'[75]) is not 'organ focused' or coercive in language and enables the intensivist to provide complete and unbiased information, support the family in their decision making and thank them for their consideration, whatever they might decide about donation.

The intensivist must ensure that the fact of death (in the situation of brain death) is understood. When (Category III) DCD is a possibility, there must be prior consensus agreement by the family and the treating team that treatment must be withdrawn before the option of possible organ donation is raised by the intensivist. The patient is clearly not dead at this time, although death is certainly anticipated to be imminent. This imminent death should also be understood by the family before the option of DCD is offered. In either situation there must be sufficient time for the intensivist to inform the family about what organ donation entails (including the subsequent benefits to transplant recipients of those organs), to answer any questions and if necessary to facilitate decision making by the family. The discussion may take into account previously expressed wishes, previous family discussions, values and beliefs of the patient and of family members. Some language is particularly insensitive from the perspective of grieving families and should be avoided[21] (e.g. the use of the term 'harvest' rather than 'organ retrieval' to describe the process of organ retrieval, or 'the body' rather than the person's name to describe the brain-dead person).

Increasingly, intensivists are being expected to facilitate the involvement of other people in this discussion – including members of organ procurement agencies and others with specific training about this discussion – with the implicit or explicit aim of 'increasing the consent rate' – most commonly to a 'target' of ~75%.[76] Various models are advocated including 'collaborative requesting', where both ICU staff and others are involved and the 'designated or trained requestor' model wherein ICU staff introduce the 'requestor' and take no part in the discussion of donation. Highly explicit strategic plans have been developed, most notably in the US, to achieve 'target consent rates'. Although such an approach has been reported to 'increase organ donation' in non-randomised time series and other observational studies,[77,78] this was not found in the only randomised study of 'collaborative requesting' so far conducted.[79] 'Repeated requesting' has been reported to increase the number of families who agree to donate and language that is variously persuasive or coercive (e.g. 'fulfilling the deceased's wishes', 'doing what he would have wanted', 'something good may come of this', 'many families take comfort in donation', 'there are many people dying on waiting lists, including in your community') might also achieve that utilitarian objective. Despite the moral distress of many intensivists, including this author, arising in response to strategic plans that, for example, 'help staff overcome obstacles, plan re-approaches, address family needs and concerns, and ensure consistency and quality in their vigorous pursuit of donation',[80] it is increasingly evident that 'conversion-rate'-focused approaches are coming to dominate the discussion of donation with families.

The intensivist should facilitate the family spending time at the bedside prior to organ removal if they wish. Some investigations (e.g. echocardiography or bronchoscopy) may be performed during this time and the family should be informed about these. The intensivist should ensure that the family is offered the opportunity to spend time with the deceased after organ removal.

MAINTENANCE OF EXTRACEREBRAL PHYSIOLOGICAL STABILITY IN BRAIN DEATH

Immediately prior to brain death there is often a limited period of hypertension, tachycardia and occasionally dysrhythmia, mediated by both autonomic activity and catecholamine secretion. Pulmonary oedema, cardiac dysfunction and myocardial injury may develop and may have implications for subsequent heart and lung graft function.[81] Treatment of this temporary sympathetic phenomenon should preferably be with short-acting beta blocker (esmolol). Cardiac arrest can rarely occur during this phase, usually due to tachydysrhythmia, but is often reversible. Hypertension is soon followed by hypotension (which may be profound in the presence of hypovolaemia or cardiac dysfunction) and can lead to cardiac arrest or loss of donor organ viability. Blood pressure should be maintained (e.g. MAP ~70 mmHg (9.31 kPa)) with inotropic support and volume expansion. Diabetes insipidus soon occurs in most but not all brain-dead persons, manifest by brisk hypo-osmolar polyuria, leading quickly to hyperosmolality and later to hypovolaemia if untreated. Other hormone abnormalities do not have therapeutic implications.[82]

After loss of cerebral metabolism there is a fall of around 25% in oxygen consumption and carbon dioxide production[83] so that less ventilatory minute volume is necessary for normocarbia. The fall in energy expenditure (heat production) together with the loss of

vasomotor tone and loss of possible thermogenesis from shivering exacerbate the risk of hypothermia.

Spontaneous movements and spinal motor reflexes commonly persist in brain death.[21] These rarely include bizarre movements,[21] which are often reproducible. Family members may be offered the opportunity to view the (perhaps second) clinical examination for brain death and should be warned about the possibility of these responses (which may not have occurred at the first examination) and given a prior explanation of them. These movements and sympathetic circulatory responses can also occur during organ retrieval in the operating room. The use of neuromuscular blockade and opioids is recommended in the operating room.[21]

STRATEGIES FOR MAINTAINING PHYSIOLOGICAL STABILITY

The onset of brain death is usually heralded by rises in intracranial pressure (if measured), hypertension and tachycardia, and progressive loss of brainstem function (coma, pupillary dilatation). These features should initiate preparation for specific support strategies, which include ensuring that central venous access, inotropic support, intravenous access for rapid volume expansion, DDAVP and a source of external heat (e.g. a warming blanket) are all available.

VENTILATORY MANAGEMENT

The aims of ventilatory management are to maintain good oxygenation and normocarbia, minimise circulatory depression and maintain, if possible, sufficiently good lung function to allow for future lung donation to occur. Usual pulmonary care including changes of position and sterile endotracheal suctioning must continue. When pulmonary dysfunction is severe, high levels of PEEP may be required to prevent airway frothing or provide adequate oxygenation. Establishing that there is apnoea at hypercarbia in such patients may require mechanical hypoventilation prior to apnoea and CPAP during it. Compared with a conventional ventilatory strategy, the use of a lung-protective strategy (including tidal volumes of 6–8 mL/kg of predicted body weight, PEEP of 8–10 cm H_2O, testing for apnoea on CPAP rather than at zero end-expiratory pressure, and closed-circuit airway suction) has been shown in a randomised controlled trial to increase the number of potential lung donors meeting suitability criteria at 6 hours (32/59 conventional vs 56/59 protective, $p<0.001$) and the number of actual lung donors (16/59 conventional vs 32/59 protective, $p=0.004$) with similar 6-month recipient survival (11/16 conventional vs 24/32 protective, not significant (NS)).[84] In a matched cohort study, oxygenation impairment remained 2 hours after an apnoea test at zero end-expiratory pressure but a recruitment manoeuvre immediately after the apnoea test was associated with no such impairment.[85] Although a Pa_{O_2} of more than 300–350 mmHg (40–46.5 kPa) on 100% oxygen and 5 cmH_2O PEEP was once thought essential for lung donation, lower Pa_{O_2}/Fi_{O_2} ratios (and higher PEEP) have been found acceptable[86] and some transplant centres have used ECMO to support (including electively) recipients of lungs with more serious but reversible impairment with acceptable outcomes.[87]

CIRCULATORY AND METABOLIC MANAGEMENT

The aims of circulatory management are to maintain adequate organ perfusion and arterial pressure without fluid overload or harmful vasoconstriction, and without prejudicing cardiac donation where this might be possible. Reasonable initial haemodynamic goals include normotension (e.g. MAP >70 mmHg (9.31 kPa)), heart rate of <100 beats per minute, and central venous pressure of ~8 mmHg (1.06 kPa). Some inotropic support is usually required. Having established normotension with an inotrope infusion, the haemodynamic response to a volume challenge should be assessed. The choice of inotrope is the subject of more controversy than evidence. Dobutamine is not recommended. Norepinephrine (noradrenaline), usually less than 500 µg/h, is preferred in Australasia (e.g. 85% of the 375 donors in 2011 in Australia and New Zealand received norepinephrine)[13] without apparent harm to organ function in recipients. Dopamine is not commonly used in Australasia (3% of 375 donors in 2011).[13] Low-dose dopamine infusion (4 µg/kg/min) has been shown in a randomised controlled trial to slightly increase urine volume (208±140 mL/h vs 178±106 mL/h, $p=0.009$) but without any effect on serum creatinine (0.82±0.29 vs 0.84±0.27 mg/dL).[88] Dopamine infusion (for ~6 hours in the donor) was associated with a slight reduction in the number of recipients receiving multiple dialyses before renal function recovered (56/227 [24.7%; 95% CI, 19.0–30.3%] vs 92/260 [35.4%; 95% CI, 29.5–41.2%]; $p=0.01$).[88] Epinephrine (adrenaline) may have specific benefit on renal blood flow in brain death,[89] but may also increase glycaemia and thereby osmotic diuresis. Catecholamine infusion may reduce the up-regulation of organ immunogenicity that occurs in brain death and lower the incidence of acute rejection in subsequent recipients of kidney grafts.[90] Although levels of thyroid hormones fall after brain death, this is probably the 'sick euthyroid syndrome' and replacement of thyroid hormone does not improve the circulation after brain death.[82] Importantly, and with more general cautionary value, this recent systematic review of the use of thyroid hormones found that benefit was shown in all 16 separate case series or retrospective audits but in none of the seven randomised controlled trials.[82] Corticosteroids are often given just prior to organ removal from brain-dead donors and commonly recommended (on the basis of retrospective analyses) to increase the number of organs, particularly thoracic organs, retrieved and transplanted. Although steroids improve haemodynamics in an experimental model,[91]

an early randomised human study[92] did not show any benefit in kidney graft outcomes. A more recent study showed that treatment of brain dead liver donors with methylprednisolone (~1.6 g over ~14 hours) did not alter the use of fluids and catecholamines compared with a no-steroid group, but was associated with lower serum levels of inflammatory cytokines in the donors, lower recipient transaminase levels in the early post-transplant period and a somewhat reduced incidence of acute rejection within 6 months (11/50 vs 19/50, $p<0.05$).[93] Two trials of the combination of steroid and tri-iodothyronine (T_3) similarly did not show beneficial circulatory effects.[94,95] Vasopressin infusion can eliminate or substantially reduce the amount of catecholamine required to support arterial pressure[95,96] without apparent detriment to subsequently transplanted organs. Control of excessive polyuria will minimise the risks of developing hyperosmolality, hypovolaemia or hyperglycaemia secondary to infusion of large amounts of dextrose-containing fluids. Synthetic desmopressin (1-D amino-8 D arginine vasopressin) is commonly given to control diabetes insipidus and appears safe and effective.[13,97] Control of diabetes insipidus is an essential aspect of rational fluid therapy, and hypovolaemia should be corrected with resuscitation fluids. Advocacy continues for use of so-called 'hormonal resuscitation'[98] (combined use of T_3, steroid and vasopressin) on the basis of reports using retrospective analysis with multiple logistic regression,[99,100] despite the negative findings of a randomised controlled trial in 80 potential cardiac donors.[95] This study did show that haemodynamic improvement occurs with time after brain death and that 14/40 hearts initially considered unsuitable for transplant were suitable 6 hours later, suggesting that a determination of unsuitability for heart donation should not be made early after brain death.

Haemoconcentration occurs early after experimental brain death. Crystalloid infusion has been reported to worsen pulmonary function in brain death and somewhat larger volumes will be required than if colloid is used.[101] At least moderate anaemia is well tolerated in brain death, but red cells may be given if needed to maintain packed cell volume at around 0.25 pending organ retrieval. Free water should be given as necessary (1–2 mL/kg per hour as 5% dextrose) to maintain serum osmolality in the range of 280–310 mOsm/kg, corresponding to serum sodium below 155 mmol/L. Severe hyperosmolality (probably a marker of inadequate donor care) is associated with poor graft function in subsequent liver recipients.[102] Low-dose insulin infusion is commonly required (e.g. 41% of 375 donors in Australia and New Zealand in 2011)[13] to prevent hyperglycaemia. Failure to control diabetes insipidus will lead to increased requirements of free water to control serum osmolality and if large amounts of 5% dextrose are used for this then hyperglycaemia and osmotic diuresis may result. Serum potassium should be kept above 3.5 mmol/L, but correction of hypophosphataemia does not improve haemodynamics in brain death.[103]

Oxygen consumption, carbon dioxide production, heat production and glucose oxidation all fall in brain death owing to the loss of cerebral metabolic activity.[83] Hypothermia may readily develop in association with vasoparesis, loss of shivering, exposure to room temperature, warm polyuria and infusion of room temperature intravenous fluids. Core temperature should be kept above the 35–36.5°C required to confirm brain death.[21] Keeping the ambient temperature high (24°C) and using infusion fluid warmers, heated humidifiers and external warming systems may be required.

AFTERCARE OF THE DONOR FAMILY

Routine aftercare is increasingly recommended[104] for all families of patients who die in ICUs. Aftercare programmes are well received[24] and have the potential to improve the care of subsequent families by revealing areas of inadequate or inappropriate communication. There may be issues specific to organ donation that need to be addressed, sometimes by way of a family meeting with an intensivist at some later stage. Most organ donation agencies provide donor families with ongoing emotional support (which may extend over many years), provide them with limited anonymous information about recipients, and accept and facilitate limited anonymous communication (i.e. by letter) between recipients and donor families by mutual consent; direct contact is not recommended.[21]

Liver transplantation

Anish Gupta, Simon Cottam and Julia Wendon

Liver transplantation has revolutionised the care of patients, with both acute and chronic end-stage liver disease. It has become an almost routine procedure, with the majority of patients having a short postoperative intensive care unit (ICU) stay and 1-year survival >90%.[1–4] Indications have widened, and contraindications decreased. As a consequence, the number of patients awaiting transplantation continues to outstrip cadaveric donor rates; waiting times lengthen, hence patients become critically ill before receiving a transplant, increasing risk and perioperative complications, and impairing long-term outcome.[5] Innovative strategies have evolved as possible solutions to the lack of cadaveric donor organs, including widening the donor pool to include previously unsuitable donors (so-called marginal donors), paediatric and adult living-related donation, reduced size and splitting techniques and the use of 'non-heart-beating donation'.

PATIENT SELECTION

There are currently relatively few absolute contraindications to liver transplantation and no specific age limitation. Listing requires a multidisciplinary consensus of a 50% chance of 5-year survival once all risks are considered. Donor organs are preciously scarce, and allocation principles must therefore take into account the severity of the recipient's condition and the perioperative risk profile. Portopulmonary and hepatopulmonary syndromes are now an active indication for transplantation as opposed to a contraindication.[6] Such patients are likely to have a more complex postoperative course, especially if graft function is borderline or they develop sepsis. Patients must have the required cardiorespiratory reserve to tolerate the procedure. Guidelines are available in regard to hepatocellular carcinoma and liver transplantation.[7,8] Such patients increasingly, if not inevitably, require disease-modifying treatments (transarterial chemoembolisation and radio-frequency ablation). Periodic imaging of the liver is mandatory to monitor disease progression whilst waiting for a suitable cadaveric donor.

Much work has gone into the development of prognostic tools to allow accurate prediction of the need and timing for transplantation, and increasingly the system used is the model for end-stage liver disease (MELD). This was initially developed for predicting survival following transjugular intrahepatic portosystemic shunt (TIPS), but has been shown to be equally useful in predicting survival in those awaiting liver transplantation. Survival depends on the physiological reserve of the recipient and the quality of the donor organ. Cardiovascular 'fitness' should remain the key determinant for receiving high-risk donor organs, which are increasingly used in order to match demand. Perioperative outcome scoring systems are becoming more robust (survival outcomes following liver transplantation (SOFT) and balance of risk score (BAR)), but are still limited to specific types of donor organs and are often disease-non-specific.[9,10] Once multi-organ failure has developed in a debilitated patient awaiting transplantation, survival rates decrease to 20–30% and these patients often require weeks to months of postoperative hospitalisation.[2,11]

Cardiorespiratory function requires detailed assessment prior to listing. There is not one specific test that will determine fitness for transplantation; however, a combination of routine blood tests, CT imaging, ECG, echocardiography, cardiopulmonary exercise testing and brain imaging if encephalopathy is a feature serves as a minimum. CT imaging may uncover underlying pulmonary pathology as well as any coronary calcification (a weak predictor of critical ischaemia). Cardiopulmonary exercise testing promulgates invaluable information of the cardiac, pulmonary and skeletal muscle-mitochondrial unit. In addition to providing dynamic information on these systems, we are able to gauge the β-adrenoceptor response and the peak oxygen consumption, which has some proven prognostic value.[12] The anaerobic threshold is frequently discussed, but is subject to major limitations – anaemia, smoking, beta-blocker therapy, exercise tolerance prior to illness, cirrhotic cardiomyopathy and hepatorenal disease. This test is not validated as a discriminator for accurately determining success in the perioperative period, but forms an integral part of each assessment. Cardiovascular disease is the third commonest cause of death following liver transplantation, after disease recurrence/chronic rejection and malignancy. The risk factors for coronary artery disease require scrupulous investigation prior to listing, particularly as obesity and diabetes may develop post-transplantation, further

increasing cardiac risk. Angiography and carotid Doppler studies must form part of the additional work-up in those patients with multiple risk factors.

Obesity is an increasingly common feature in patients listed for transplantation, and non-alcoholic steatohepatitis is the only indication for transplantation that is rising in frequency, soon to be the leading indication. The associated co-morbidities need to be quantified, and the overall risk profile cautiously considered prior to listing. Postoperative complications including infection, wound dehiscence, and ventilator dependency are more prevalent, with cardiovascular complications the main cause for mortality. Obese patients with diabetes or coronary artery disease are 40% less likely to reach 5-year survival.[13] However, even transplanted obese patients show a survival benefit over those on the waiting list despite their higher complication rate, and this provides a difficult ethical debate over resource allocation.[14] There are no thresholds in body mass index for listing. Optimisation prior to surgery should focus on controlling medical co-morbidities as well as weight loss and dietary changes.[15]

HEPATIC SYNDROMES

Changes in the cardiovascular system associated with chronic liver disease may contribute to the spectrum of cardiopulmonary disease associated with chronic liver disease and portal hypertension. A hyperdynamic state with high cardiac output, long-standing portal hypertension with the development of collateral flows, together with an imbalance of vasoactive mediators either synthesised or metabolised by the liver, may lead to characteristic changes in both flow and pressure through the pulmonary vasculature. This may be associated with hypoxia and orthodeoxia. Two ends of the spectrum are hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH). The two conditions are uncommon but important, as they have vastly different impacts on risk associated with liver transplantation and long-term outcome (**Table 101.1**). The role of agents used in the management of primary pulmonary hypertension is yet to be examined in a controlled manner in liver disease, but data thus far suggest benefit.

HEPATOPULMONARY SYNDROME

HPS is present in approximately 20% of cirrhotic patients. It can be seen from Table 101.1 that hypoxia is a characteristic finding in this condition. It results from intrapulmonary vascular dilatation at the pre- and post-capillary level, leading to decreased ventilation/perfusion ratios; more uncommonly, anatomical shunt is present with arteriovenous communication. One of the postulated mechanisms of this vasodilatation is overactivity of pulmonary vasculature nitric oxide synthetase; pre-transplant patients have raised levels of exhaled nitric oxide that decrease post transplant with resolution of the syndrome. Diagnosis is confirmed by contrast-enhanced echocardiography or radionuclide lung perfusion scanning. Medical treatment of the syndrome has been disappointing; indeed, most transplant centres agree that the syndrome is an indication for transplantation in itself, as resolution is reported in up to 85% after transplantation.[16] Risk stratification based on severity is important, as vastly increased peri-transplant mortality is associated with severe hypoxia and high levels of vascular shunt. Severe hypoxia qualifies for MELD exception prioritisation. Mortality overall is 16% at 90 days and 38% at 1 year. Predictors of mortality in this group are severe hypoxia (Pa_{O_2}<6.5 kPa (<50 mmHg)) and shunt fraction >20%.[16] Refractory hypoxia is the indirect cause of death, which may be due to multi-organ failure, intracerebral haemorrhage and sepsis due to bile leaks. Whilst it is true that the recipient's organs are conditioned to function in the chronic pre-operative hypoxic state, the liver graft must be protected from hypoxia immediately following transplantation, with a gradual weaning of oxygen levels. Resolution of the syndrome is variable and can take up to 1 year, lending support to the theory that it is vascular remodelling rather than just acute reversal of vasodilatation that reverses hypoxia.[17,18]

Table 101.1 Diagnostic criteria for hepatopulmonary syndrome and portopulmonary hypertension

HEPATOPULMONARY SYNDROME	PORTOPULMONARY HYPERTENSION
Chronic liver disease (±cirrhosis)	Portal hypertension
Arterial hypoxaemia	Mean pulmonary artery pressure >25 mmHg (3.33 kPa)
PaO_2<75 mmHg (10 kPa) or A–a O_2 gradient >20 mmHg (2.66 kPa)	Pulmonary artery occlusion pressure <15 mmHg (2 kPa)
Intrapulmonary vascular dilatation	Pulmonary vascular resistance >120 dynes/s per cm^{-5}

PORTOPULMONARY HYPERTENSION

Up to 20% of pre-transplant patients have pulmonary hypertension; this probably constitutes increased flow through the pulmonary vasculature and is not associated with increased resistance. These patients do well after transplantation. A much more ominous syndrome is the presence of pulmonary hypertension with high pulmonary vascular resistance (seen in <4%). The aetiology of this syndrome is complex but it is characterised by a hyperdynamic high flow state with excess central volume and non-embolic pulmonary vasoconstriction. The pathological changes associated with this

syndrome match those associated with primary pulmonary hypertension except that cardiac output is high in this group.

In comparison with HPS, there are several differences in terms of response to medical treatment and outcome after transplantation. The response to epoprostenol, a PGI_2 analogue, is encouraging. Decreases in pulmonary artery pressure but more importantly transpulmonary gradient (TPG) have been noted, although at least 3 months' treatment seems necessary, suggesting remodelling rather than vasodilatation is the important mechanism. A limiting factor in the treatment may also be progressive thrombocytopenia and splenomegaly. Endothelin receptor antagonists (bosentan, ambrisentan) have been shown to almost normalise PVR in selected patients by blocking the vascular reactivity of the pulmonary vascular bed. Phosphodiesterase inhibitors (e.g. sildenafil) increase the availability of nitric oxide within the pulmonary vasculature. These oral agents hold some advantage for outpatient management; however, intravenous prostacyclin remains the treatment of choice in severe cases.[19]

Another difference is the perioperative risk and post-transplant prognosis. Resolution is not associated with transplantation and progression can be a feature. Perioperatively, the higher the mean pulmonary artery pressure (MPAP), pulmonary vascular resistance (PVR) and TPG the greater is the risk of death, which is usually due to acute right ventricular decompensation. Right heart pressures need to be closely monitored with pulmonary artery catheterisation preferably commenced preoperatively to establish prostacyclin infusion. Milrinone may be added to gain further control of pulmonary pressures in the perioperative process. TOE monitoring provides invaluable assessment of right heart function, and enables more accurate volume replacement during reperfusion. If the MPAP is >35 mmHg (4.66 kPa) or the PVR is >250 dyne/s per cm (250 mN/m), mortality reaches 40%. If MPAP is >50 mmHg (6.66 kPa) some have even suggested delisting or even intraoperative cancellation as the mortality may be as high as 100%.[20] Intravenous pulmonary vasodilators are usually weaned to oral medications, which about half will require long term. Resolution in the remaining half occurs over several months.[19]

HEPATORENAL SYNDROME

Hepatorenal syndrome (HRS) is a potentially reversible cause of renal dysfunction in a small proportion of acute kidney injury (AKI) cases with cirrhosis. Two subtypes exist: type 1 results in acute renal deterioration following a precipitating event (sepsis, post-paracentesis syndrome), whereas type 2 is a progressive form occurring over weeks. It represents an advanced stage of haemodynamic dysfunction, characterised by splanchnic vasodilatation, reduced systemic vascular resistance and reduced effective arterial blood volume.

Box 101.1 Diagnostic criteria for hepatorenal syndrome[22]

Cirrhosis with ascites
Serum creatinine >133 µmol/L (1.5 mg/L)
No improvement in serum creatinine (to <133 µmol/L) after 2 days of diuretic withdrawal and albumin replacement (1 g/kg per day or maximum 100 g/day)
Absence of shock
Absence of nephrotoxic drugs
Absence of renal parenchymal disease

This contraction in central blood volume stimulates a powerful neuroendocrine response mimicking volume depletion and predisposing to prerenal failure (hepatorenal syndrome).[21] The diagnosis is essentially one of exclusion in a patient with cirrhosis (**Box 101.1**).[22] The prognosis of HRS is poor with the worst survival rates out of all the causes of AKI (3-month survival for type 1 is 20%, and type 2 is 40%). Vasoconstrictor agents, albumin, transjugular intrahepatic portosystemic shunts and improved antimicrobial therapy have all proven benefits in serving as a bridge to transplantation.

Transplantation is the only treatment for HRS, with normalisation of sodium excretion, serum creatinine and neurohormonal levels occurring within 1 month. The renal vasoconstrictive indices require 12 months before recovering. HRS does increase the complication rate and reduce survival following transplantation, with renal function never recovering in up to 25%. Those on renal replacement therapy for more than 8 weeks prior to transplantation should be offered combined liver–kidney transplantation. Interestingly, the risk of acute rejection for combined liver–kidney grafts is the same as for liver transplantation, as compared with the higher rate of rejection that is seen for renal transplant alone.[22–24]

EXTRACORPOREAL HEPATIC SUPPORT

The liver has metabolic, excretory and synthetic functions, all of which need to be maintained in a patient who has liver failure until either an organ becomes available or regeneration takes place. Two groups of devices are available; purely mechanical devices provide detoxification whereas bioartificial devices, which require an abundant source of hepatocytes, also provide synthetic and biotransformation activities. Artificial devices include plasma exchange and albumin dialysis, which may incorporate extracorporeal albumin dialysis (MARS (molecular adsorbents recirculating system, Gambro)) or fractionated plasma separation and absorption (Prometheus). Clinical trials are in progress to evaluate the place for these devices. To date, none of these artificial devices has conferred a survival benefit in liver failure in prospective randomised trials,

though there has been some success with improvements in neurological status and reduced cerebral oedema.[25–27] Bioartificial devices suffer from limited hepatocyte supply and prospective clinical trials conveying survival benefits, though some early results may prove promising. In addition to efficacy, still to be elucidated is the timescale over which these devices can be used and whether they can bridge the gap to regeneration, thus sparing the patient from transplantation.

PERIOPERATIVE ASPECTS

OPERATIVE TECHNIQUE

Orthotopic liver transplantation (OLT) involves recipient hepatectomy, revascularisation of the donor graft and biliary reconstruction. Two main techniques are used in adult liver transplantation: those with vena cava preservation ('piggyback technique') and those using portal bypass (either internal, temporary portocaval shunt or external, veno-venous bypass). The advantages of the piggyback technique include haemodynamic stability during the anhepatic phase, without large-volume fluid administration, and the negation of the need for veno-venous bypass with its associated risks and complications. Decreased transfusion requirements, shorter anhepatic time and shorter total operating time are also observed. There is no observed difference in renal function between the two techniques.[28–30] The donor hepatic artery is directly anastomosed, utilising an 'end-to-end' technique, or a conduit is constructed. Portal venous anastomosis must also be undertaken; in most patients this is an end-to-end anastomosis. Portal venous thrombosis is no longer a contraindication to transplantation and these patients may undergo a recannulisation procedure or require a jump graft technique. Such conduits and grafts are normally fashioned from donor vessels.

It is imperative that all those caring for the patients are aware of the surgical technique undertaken, as complications may vary. The radiologist must be aware of the technique used to allow appropriate interpretation of subsequent investigations and vascular imaging. This applies not just to the vascular anastomosis but also to the presence of a full graft, reduced size graft, right or left split graft or indeed an auxiliary graft. The biliary anastomosis is normally also undertaken as an end-to-end procedure, the donor bile duct being directly joined to the recipient duct. It is no longer standard for this to be undertaken over a T-tube, but this may be required where there is marked discrepancy between donor and recipient duct size. Some conditions (e.g. extrahepatic biliary atresia, primary sclerosing cholangitis) may preclude end-to-end anastomosis and formation of choledochojejunostomy may be required.

Split-liver grafts allow one liver to provide an organ for two recipients. Initially comprised of a child receiving the left lateral segment and an adult the remaining liver, nowadays two adults may receive grafts from one liver if the anatomy and size match allow. Such splits may be less than ideal when the recipient has a high MELD score, as is increasingly the case with the prioritisation of sick patients awaiting liver grafts. Such grafts are at increased risk of postoperative complications such as bile leaks and haematoma/collections at the cut surface.[3,31]

Auxiliary liver transplantation is a technique that involves subtotal recipient hepatectomy and implantation of a reduced size graft. It is a technically difficult procedure, as both portal and arterial supplies have to be constructed de novo. In addition, a duplicate biliary drainage system needs to be constructed. Hepatic venous outflow is anastomosed as usual. In acute liver failure, it has significant potential, since regeneration of the native liver may obviate the need for donor function, potentially allowing withdrawal of immunosuppression. It also has application in the treatment of some hereditary metabolic disorders where adequate metabolic function may be achieved with an auxiliary graft. The major advantage is withdrawal of immunosuppressive therapy if the patient develops severe complications, or when applicable gene therapy becomes available. The disadvantage of auxiliary transplantation in the face of acute liver failure is that the postoperative course is frequently more complicated; reasons are multifactorial, and failure can be due to the continued presence of a regenerating native liver or due to a smaller donor graft attempting to cope with a critical illness.

Non-heart beating transplantation (NHBD) has emerged in recent times as a potential way of increasing organs for transplantation.[32,33] The success in renal transplantation has led to exploration of its application in the fields of liver, pancreas and lung retrieval. Most retrievals are undertaken in the context of controlled NHBD (i.e. in the context of planned withdrawal of care). Warm ischaemia can be accurately assessed and cold ischaemia minimised. Early experience with NHBD was associated with inferior survival for patients and grafts but recent experience suggests that survival is approaching that for heart-beating donation. There are, however, continuing concerns over biliary and vascular complications. Prolonged cold ischaemia is associated with poor graft function and biliary complications, as are warm ischaemia times of greater than 30 minutes.[34] With regard to postoperative care, an understanding of the pre- and perioperative factors is essential in anticipating potential complications, initiation of monitoring and proactive management.

Living donor-related transplantation (LDRT) is now a routine undertaking in paediatric liver transplantation. It is becoming increasingly utilised in adult liver transplantation although its application in countries with good cadaveric donor pools is less established. Adult LDRT using right lobe grafts is an effective procedure with good survival outcomes, but is associated

with significant complications. From a postoperative perspective the intensive care team may be responsible for the management of both the donor and the recipient. Morbidity rates for donors are significantly higher with use of a right lobe donation compared with a left lobe graft. Mortality for donors has been reported. Survival rates now reported for living related recipients are good, with rates of 80% at 12 months.[35,36]

Adequate function of undersized transplanted liver grafts is essential to successful outcome. Primary graft non-function is relatively rare and one of the main areas of concern is that of the so-called 'small for size syndrome'.[35,37] This was first recognised in the post-transplant setting but also occurs following liver resection. It is still an area under discussion but the clinical entity is that of hyperbilirubinaemia, graft dysfunction, ascites and portal hypertension with associated end-organ dysfunction/failure. The clinical picture is that of portal hyperaemia, with portal flow passing into a small liver remnant/graft with associated pathophysiological consequences, and at a histological level there is evidence of arteriolar constriction. In some patients consideration should also be given to the potential compounder of hepatic venous outflow limitation.[38,39] Other factors that predispose to the syndrome are an inappropriate graft weight to recipient and steatotic grafts. In regard of management of this syndrome most trials have focused on optimising venous outflow and limiting/preventing portal hyperaemia and limiting portal hypertension.[35,40] Animal studies have also examined the role of intrahepatic vasodilators with good effect. Management of the syndrome remains controversial but its early consideration allows the clinical team time to consider therapeutic options and interventions.

INTRAOPERATIVE MONITORING

In addition to routine monitors, invasive arterial blood pressure and central venous pressure measurements are invaluable. With modern advances in technology, it has now become routine practice to use some method of cardiac output monitoring. The trends in stroke volume variation and cardiac index can be used as a guide to fluid delivery, and to help gauge requirements for vasopressors and inotropes. The use of trans-oesophageal echocardiography (TOE) is often reserved for patients with known pulmonary hypertension, though this is gradually being used more frequently to assess fluid status, regional wall motion abnormalities, the presence of intracardiac thrombi, and even to locate the position and patency of transjugular intrahepatic portosystemic shunts (TIPS).[41,42]

FLUIDS, HAEMORRHAGE AND COAGULATION

There is no consensus on the amount or type of fluid that should be used during liver transplantation. The centrally deplete fluid compartment, if aggressively filled, will rapidly redistribute to the peripheral and portal circulation, exacerbating haemorrhage.[43] Incremental volume replacement is the key, ideally guided by some form of flow monitoring. Large volumes of crystalloids must be avoided to prevent excessive interstitial oedema. The choice of colloid remains an important topic of debate and ongoing research. The following points should be remembered when deciding which colloid to infuse. Starches with a molecular weight above 200 kDa may predispose to acute kidney injury and result in pruritus. Starches may remain within the intravascular compartment for longer than gelatines; however, this effect is questionable with modern, lower-molecular-weight starches.[44]

Orthotopic liver transplantation may be associated with massive blood loss. The causes are multifactorial and include preoperative coagulopathy secondary to end-stage liver disease, portal hypertension, surgical technique, adhesions related to previous surgery and intraoperative changes in haemostasis. The degree of clinical coagulopathy is impossible to predict, and relies on the imbalance in antihaemostatic and prohaemostatic drivers.[45] The low-grade fibrinolytic process in advanced cirrhotics may be exacerbated during surgery, particularly during the anhepatic and reperfusion stages. Platelet dysfunction, both quantitative and qualitative, is also common though the impact on haemostasis is variable.[46] The consequences of massive bleeding and replacement are significant, not only in terms of postoperative morbidity and mortality, but also intraoperatively when issues such as acute hypovolaemia, reduced ionised calcium due to elevated citrate levels, hyperkalaemia, acidosis and hypothermia become important. Transfusion-related acute lung injury (TRALI) is a potentially devastating complication. It is believed to result from neutrophil antibodies preformed in donor serum. The immunosuppressive effects of large-volume blood transfusions are well recognised and pertinent in a group of patients who are already functionally immunosuppressed. In addition to these immediate problems is the risk of transmission of, as yet, unidentified viral infection.

Much effort has gone into reducing the amount of exogenous blood products required intraoperatively. This includes the use of cell salvage techniques with autologous transfusion and frequent testing of haemostasis, utilising both laboratory-based tests and thromboelastography or rotational thromboelastometry. The prophylactic use of tranexamic acid may attenuate the degree of fibrinolysis during the early stages of transplantation. The severe post-reperfusion fibrinolysis often resolves once the donor liver begins to function and seldom requires immediate correction. Optimisation of clot stability with fibrinogen prior to coagulation factor and platelet replacement has led to reduced transfusion requirements in major haemorrhage. Fibrinogen and prothrombin complex concentrates are

gaining popularity due to the reduced volume load and superior efficacy, though these products are not universally licensed or readily available. They are purified and virally inactivated by nature of the manufacture process, reducing the risks of viral transmission and TRALI.[47] There is a paucity of evidence-based thresholds for platelet transfusion, and the benefits in reducing haemorrhage and improving liver regeneration must be balanced with the adverse risks of ischaemia-reperfusion injury, TRALI and reduced survival.[46] These therapies must be judiciously employed in order to control bleeding at the potential expense of thromboembolic complications which may be as high as 4%.[41]

Although it is assumed that all patients with liver disease are subject to an increased risk of bleeding there are subgroups that are prothrombotic, as evidenced clinically and with thromboelastography. Patients with preoperative portal or hepatic venous thrombosis appear to carry a higher incidence of prothrombotic mutations than the general population, and patients with primary biliary cirrhosis and primary sclerosing cholangitis are frequently prothrombotic. Such patients may require anticoagulation in the early postoperative period. Other patient groups such as those with Budd–Chiari syndrome may have a recognised prothrombotic condition with a resultant early requirement for anticoagulation.

Electrolyte disorders are common in advanced liver disease, and careful monitoring of sodium, potassium and calcium levels is paramount. Hyponatraemia is associated with increased mortality in the pre-transplanted patient, and rapid changes in the perioperative period may lead to further morbidity (although mortality appears comparable).[48] Rapid changes in sodium concentration have been linked to rare cases of central pontine myelinosis. Calcium is required for haemostasis, and requires supplementation especially if citrated products have been administered. Life-threatening hyperkalaemia may develop on reperfusion, and must be anticipated and managed immediately. Cell-salvage apparatus can be used to wash the packed red cells to eliminate excess citrate and potassium administration.

POST-REPERFUSION SYNDROME

The post-reperfusion syndrome is a poorly understood phenomenon that occurs after reperfusion of the portal vein through the donor graft. It is characterised by hypotension, bradycardia, vasodilatation, pulmonary hypertension, hyperkalaemia and in some cases cardiac arrest. The aetiology is unclear, but a sudden increase in venous return, release of vasoactive substances, and cold potassium-rich preservation fluids are potentially implicated. The syndrome usually resolves within the first 5 minutes of reperfusion with appropriate fluid loading and electrolyte management. However, in approximately 30% of patients it lasts for significantly longer, necessitating the use of inotropes and/or vasopressors. The post-reperfusion syndrome seems more common in organs with longer preservation times and may well be associated with initial poor graft function.

POSTOPERATIVE CARE

The postoperative care of the recipient depends to some extent on preoperative co-morbidity, the presence of any of the immediate complications listed above, recipient stability during the procedure and lastly the pretransplant cause of liver failure. Straightforward recipients who return to the ICU in a stable condition with good graft function may be woken up and weaned immediately. The tracheal tube and some of the invasive monitoring lines should be removed as soon as no longer required to reduce the risk of infection and encourage mobility. Close monitoring of all physiological systems is important in the early postoperative period (**Tables 101.2** and **101.3**).

EARLY COMPLICATIONS

As with all postoperative surgical intensive care admissions, some complications are applicable to all patients. These include haemorrhagic and pulmonary complications of any prolonged procedure in addition to specific complications pertinent to liver transplantation. These can be subdivided into technical complications, conditions and complications associated with pre-existing liver disease, and complications associated with immunosuppressive agents, graft function and massive transfusion.

CARDIOVASCULAR

End-stage liver disease is characterised by a hyperdynamic circulation, with low systemic vascular resistance, high cardiac index and a proportionately reduced central circulating volume. The majority of patients can be managed with judicious volume loading with or without vasopressors to maintain adequate perfusion

Table 101.2 Routine investigation of post-transplant patient in the ICU

	FBC	LFTS	COAGULATION	DRUG LEVELS	CULTURES	ULTRASOUND
Day 1	√	√	√		As indicated	Routine ultrasound including hepatic artery, hepatic
Day 2	√	√	√	√	As indicated	and portal venous flow D1 and D5, and if
Day 3	√	√	√	√	As indicated	clinically indicated at other times

Table 101.3 Monitoring of graft function in ICU

PARAMETER		COMMENT
GENERAL	Liver perfusion	Characteristics at surgery
	Bile production	Quality±volume if T-tube in situ
	Haemodynamics	Stabilisation, with cessation of vasopressor requirements
COAGULATION	INR/prothrombin time	8-hourly for first 24 hours, thereafter daily unless indicated. Fall in PT is more important than the actual value. FFP should be withheld to assess graft function although platelets given as indicated
BIOCHEMISTRY	Glucose	Hypoglycaemia is an ominous sign. 4-hourly for first 24 hours. Euglycaemia/hyperglycaemia requiring insulin infusion is normal
	Arterial blood gases and lactate	4–6-hourly depending on ventilatory requirement. Hyperlactataemia and acid–base disturbance should rapidly resolve. Other causes of base deficit such as renal tubular acidosis and hyperchloraemia should be excluded and managed appropriately
	AST	Should fall steadily (50% fall each day). The first measurement may reflect washout and thus the next may be higher. Daily measurements. The initial measurement reflects the degree of preservation injury
	Bilirubin	Early increases may reflect absorption of haematoma and do not reflect graft function. Haemolysis should be considered if the graft is not blood group matched, termed passenger lymphocyte syndrome
	ALP/GGT	Usually normal; increases may reflect biliary complications or cholestasis of sepsis

pressures. However, in some patients this state may compensate for degrees of cirrhotic cardiomyopathy, characterised by systolic and diastolic dysfunction, electrophysiological abnormalities and a blunted β-adrenoceptor response.[49–51] The massive increase in the volume of liver transplants performed in the last decade has revealed cardiac failure as an important cause of morbidity and mortality in the transplant recipient.[52] OLT can impose severe stresses on the cardiovascular system; haemorrhage, third-space loss, impaired venous return due to caval clamping, hypocalcaemia and acidosis impair myocardial contractility. Reperfusion can also be a time of profound circulatory instability. Rapid fluctuations in filling pressures place the compromised and stressed myocardium at risk of failure. In addition, the impaired exercise tolerance of the pre-transplant recipient may have limited the clinical importance of coronary ischaemia, which becomes pertinent in the post-transplant period.

Haemodynamic changes after OLT are also common; hypertension with an increased systemic vascular resistance is frequent and may be due to the restoration of normal liver function and portal pressure, as well as the hypertensive effect of the calcineurin immunosuppressants. The increased afterload in the early post-transplant period may unmask cardiac dysfunction. Management of myocardial failure post OLT is largely empirical; diuretics, afterload reduction and positive-pressure ventilation may all be required. In the longer term, control of cardiovascular risk factors is required and many of these patients may over the years return to the intensive care environs with other system failures and considerable burdens of hypertension, coronary ischaemia, diabetes, hyperlipidaemia and renal dysfunction.

PULMONARY

Pulmonary complications are common and occur in 40–80% of recipients. The presence of preoperative impairment (e.g. pleural effusions, hypoxaemia, pulmonary hypertension or the hepatopulmonary syndrome) is strongly associated with postoperative complications. Specific conditions related to liver transplantation include right hemidiaphragm palsy as a result of phrenic nerve damage, which can occur if suprahepatic caval clamping is used intraoperatively. The commonest postoperative problems are pleural effusions, ongoing shunting secondary to the hepatopulmonary syndrome, atelectasis and, over subsequent days, infection. De novo acute respiratory distress syndrome is relatively uncommon at this stage. Other complications such as TRALI and pulmonary oedema are almost certainly under-recognised and underreported.

Specific management of portopulmonary syndrome may be required in the postoperative period if right-sided pressures are elevated, to ensure that liver congestion and graft dysfunction do not ensue.[6,50,51] Control of pulmonary pressures may require a variety of therapeutic options, with the treatment options being similar to those utilised in primary pulmonary hypertension. Concern about potential hepatotoxicity needs to be balanced against the need to control right-sided pressures and provide optimal graft function. Similarly, hepatopulmonary syndrome may take a variable time to resolve and hypoxia during this period will require management and recognition. Respiratory complications are also seen in patients with poor muscle bulk and subsequent weakness. Similarly, the presence of osteoporosis in the pre-transplant patient is frequently associated with postoperative pain and poor cough.

The role of adequate analgesia is important, as in all patients, in promoting mobilisation and adequate respiratory function. In general, the management of a protracted respiratory wean follows conventional lines.

NEUROLOGICAL

The quoted incidence of central nervous system (CNS) complications varies widely from 10 to 40% in the published series. Most neurological complications occur within the first month of transplant. The commonest causes relate to persistence of pre-existing encephalopathy.[53,54] The causes are multiple, including hepatic, metabolic, infectious, vascular and pharmacological. A patient with acute liver failure will remain encephalopathic in the immediate post-transplant period, and is at risk of intracranial hypertension for 48 hours following transplantation, or longer in the face of graft dysfunction. De novo hepatic encephalopathy may develop in patients with severe graft dysfunction and/or primary graft non-function; again the patient is at risk of cerebral oedema. The effects of sepsis, rejection (and its treatment with high-dose steroids), drug therapy (especially the sedatives and analgesics used in the ICU setting) and the presence of renal failure may all contribute to the presence of altered conscious level. The calcineurin inhibitors are particularly associated with seizures and altered conscious level. All such patients will require brain imaging to further define the aetiology of their impaired neurology.

Other possible neurological complications are those of intracerebral haemorrhage. Such bleeds may relate to arteriovenous malformations, may be spontaneous or may be a complication of intracranial pressure monitoring, particularly in patients with acute liver failure. CNS infection normally presents later than the immediate postoperative period but should always be considered, especially in those patients with a prolonged and complicated postoperative course. All possible infecting agents, including bacterial, viral, fungal and opportunistic, should be considered. Central pontine myelinosis is a rare but potentially devastating complication associated with rapid sodium shifts. Modern technology and the use of haemofiltration techniques allow tight control of sodium shifts in the majority of patients, and this has become a rare neurological complication.

RENAL

Despite intraoperative efforts, renal dysfunction often progresses and acute renal failure is a relatively common complication, with an incidence of between 12 and 50% and a multifactorial aetiology.[55–57] Risk factors include the presence of pre-transplant co-morbidity (e.g. hypertension, diabetes mellitus, hepatorenal syndrome), severity of underlying liver disease, intraoperative instability, blood product requirement, drug toxicity and graft dysfunction. Mortality in those who require renal replacement is high, and graft survival is lower. To avoid exacerbation of existing renal impairment, agents with inherent nephrotoxicity, such as the calcineurin inhibitors, may be omitted or their dose significantly reduced in the early pre-transplant period. There must be a balance between the risk of rejection and that of side-effects of drug therapies. Mycophenolate mofetil, a cytotoxic immunosuppressant, may be substituted in the post-transplant course to limit or protect against renal dysfunction, and increasingly agents such as interleukin-2 (IL-2) blockers are utilised to decrease renal dysfunction.[58]

Intra-abdominal hypertension should always be considered in the post-transplant setting as a potential contributor to not only renal dysfunction but also cardiorespiratory embarrassment. Early consideration should be given to laparostomy in patients with elevated intra-abdominal pressures and associated organ dysfunction.[59,60]

PRIMARY NON-FUNCTION

This is a spectrum occurring in 2–23% of cases, which at worst requires urgent retransplantation. It is characterised by poor graft function from the time of reperfusion, with hyperlactataemia, coagulopathy, metabolic acidosis, hypoglycaemia, hyperkalaemia and a rapid elevation in aminotransferase concentrations, accompanied by a systemic inflammatory response. A major reason for the initial graft dysfunction is ischaemic injury to the graft, which depends on the type of preservation fluid used, and the duration of cold and warm ischaemia time. The aetiology of primary non-function remains unclear.[61] Vasodilator prostaglandins and antioxidants may have a role in 'rescue therapy', but controlled data are lacking.

SURGICAL PROBLEMS

Anastomotic thromboses are uncommon complications of liver transplantation, but can cause significant morbidity, which may require further invasive procedures and even urgent retransplantation. Hepatic artery thrombosis occurring in the early postoperative period is associated with a similar picture to PNF. Small vessel calibre is a risk factor, and is more prevalent in the paediatric recipient where it has also been associated with prothrombotic states such as protein C deficiency. Ultrasound is the first-line screening test and is undertaken both routinely in the immediate postoperative period and if there is a sudden rise in transaminase measurements. If the vessel is not visualised, the patient should proceed to CT angiography. If diagnosed quickly, emergency intervention can be undertaken to re-establish arterial flow; however, emergency retransplantation may be required.

Venous complications such as portal thrombosis are even less common, and are usually associated with intraoperative technical difficulty, recurrence of

preoperative disease or undiagnosed thrombophilia. Portal thrombosis is normally associated with portal hypertension and massive ascites, but may also be associated with graft dysfunction, especially in the paediatric population. CT scanning will interrogate the vessels and also provide information on graft perfusion; regional ischaemia may be identified that may have presented as a transaminitis. Treatment is dependent on the severity of the injury but ranges from diuretics to angioplasty, surgical reconstruction or ultimately retransplantation. Regional ischaemia and areas of poor perfusion should be actively sought in patients with a transaminitis and especially in those who had received a reduced size or split-liver graft.

Biliary complications after liver-transplant are relatively common. The bile duct normally receives two-thirds of its arterial supply from the gastroduodenal artery and one-third from the hepatic artery. Post-transplant the only supply is from the hepatic artery, making it vulnerable to ischaemic injury whether that be at the time of retrieval, reperfusion or postoperatively. The resulting complication depends on the type of biliary anastomosis and the timing of the insult. Strictures are more commonly observed than leaks. Management of biliary complications is in the first instance endoscopic, with stent placement and/or balloon dilatation. In patients with a T-tube in situ, cholangiography may be undertaken by that route. Open reconstruction in the early postoperative period is uncommon (**Tables 101.4** and **101.5**, **Box 101.2**). Bile leaks may also be seen in the postoperative period from the cut surface of a split graft; they are associated with an increased risk of infection and potentially of pseudoaneurysm formation.

ACUTE REJECTION

Acute cellular rejection becomes a risk from approximately 5–7 days post transplant; the clinical signs of rejection are non-specific and include fever, deterioration in graft function and a rapid rise in serum aminotransferase concentration. Liver biopsy is the only

Box 101.2 Differential diagnosis of graft dysfunction in ICU

Primary non-function	Drug-induced liver dysfunction
Preservation injury	Infection – viral, bacterial, fungal
Rejection – hyperacute/ acute	Recurrent disease (normally late)
Vascular complications	
Biliary complications	

Table 101.4 Technical complications of OLT

COMPLICATION	COMMENT
ABDOMINAL BLEEDING	
Anastomosis	Immediate
Graft surface (if cut down)	Immediate
General ooze secondary to coagulopathy	Immediate
Pseudo-aneurysm formation	Can present early or late and is usually associated with intra-abdominal sepsis and biliary leaks
VASCULAR COMPLICATIONS	
Hepatic artery thrombosis	Early and late
Portal vein thrombosis	Early and late; there may also be a stenosis of the portal vein rather than thrombosis
Inferior vena cava obstruction	May be infra-, supra- or retrohepatic in site
BILIARY COMPLICATIONS	
Biliary leak	Usually early
Biliary stricture	Usually late
Papillary dysfunction	Late
Roux-en-Y dysfunction	Usually late

Table 101.5 Biochemical and clinical features of technical problems

COMPLICATION	FEATURES	INVESTIGATION	MANAGEMENT
HEPATIC ARTERY THROMBOSIS	Early: rapid rise in transaminase, coagulopathy, graft failure Differential diagnosis: hyperacute rejection, primary non-/dysfunction	Ultrasound, angiogram	Thrombectomy, retransplantation
	Late: biliary complications, strictures, sepsis, liver abscess	Ultrasound, angiogram	Angioplasty
PORTAL VEIN THROMBOSIS	Early: rapid deterioration in graft function, acute liver failure, ascites, variceal bleeding	Ultrasound, CT, angiography, MRA	Thrombectomy, retransplantation, conservative management
	Late: mildly abnormal LFTs, portal hypertension, varices	Ultrasound, CT, angiography, MRA	

Table 101.6 Management of rejection in intensive care

	COMMENT	CHARACTERISTICS	LIVER BIOPSY	DIFFERENTIAL DIAGNOSIS	TREATMENT OPTIONS
HYPERACUTE REJECTION	Rare in OLT 1–10 days post-transplant	Rapid deterioration in graft function: AST > 1000 Coagulopathy, acidosis	Haemorrhagic necrosis	Primary non-function/ delayed function Hepatic artery thrombosis	Retransplantation Rarely: OKT3, cyclophosphamide, plasmaphoresis (unproven)
ACUTE REJECTION	30–70% Occurs at mean of 7–9 days	Often clinically silent apart from fever and RUQ pain High AST and bilirubin Coagulation and acid–base undisturbed	Portal inflammation Endotheliitis Bile duct damage	Sepsis Vascular Viral	Methylprednisolone 1 g daily for 3 days

In those who do not respond: Consider diagnosis; if correct, consider tacrolimus if induction agent is ciclosporin A, OKT3 or MMF/ sirolimus (rapamycin) if other new agents.

reliable diagnostic tool; however, biopsy may be relatively contraindicated owing to coagulopathy. In some circumstances transjugular biopsy offers a solution to this problem. The normal management regimen for an episode of acute rejection is that of pulsed methylprednisolone, 1 g for 3 days. The differential diagnosis may be that of sepsis, or problems with vascular integrity; there are some data to suggest that procalcitonin may be of use in the differentiation (**Table 101.6**).

INFECTIOUS COMPLICATIONS

Transplant recipients are uniquely vulnerable to bacterial infection: preoperative colonisation, prolonged and technically difficult surgery, large wounds, urinary catheterisation and the frequent need for central venous access postoperatively all combine to make them at vastly increased risk. However, compared with a decade ago, the overall incidence is reduced, probably owing to improved and patient-tailored immunosuppressive regimens. Sepsis remains an important and lifelong complication of liver transplantation, which may require readmission to intensive care.[62,63]

The epidemiology of pathogens is evolving; the incidence of Gram-positive bacterial infection (enterococci and staphylococci) is now more common than Gram-negative sepsis. More concerning is the emergence of multiple antibiotic-resistant bacteria, in particular meticillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE) and extended-spectrum beta-lactamase (ESBL)-producing Gram-negative organisms. Mortality and graft failure associated with infection caused by these multiply resistant organisms is significantly greater compared with other organisms.[64] A decline in the incidence of both *Pneumocystis jiroveci* (formerly *P. carinii*) and cytomegalovirus infection is probably a result of both modulating immunosuppressive regimens and more effective prophylaxis. Patients should be screened for viral infections, including herpes simplex virus (HSV) and cytomegalovirus (CMV) utilising polymerase chain reaction (PCR) techniques. Opportunistic fungal infection still remains problematic, especially in the context of environmental risk factors (**Table 101.7**).[65,66]

FEVER

In transplant recipients, 76% of febrile episodes have a documented infectious aetiology, but acute rejection needs to be considered in the differential diagnosis. In the ICU transplant recipient the aetiology is even more likely to be infectious – often nosocomial and bacterial. In one study, pneumonia, catheter-related bacteraemia and the biliary tree were the three most common sources in the ICU population (41%). Viral infections accounted for 9% of febrile episodes, fungal infections 3% and endocarditis 3%. As mentioned above, the epidemiology of pathogens is changing and it is important to have thorough knowledge of local problem pathogens on which to base meaningful antibiotic policy. These data have implications for the threshold to investigate febrile episodes, suspect bacterial infection and commence appropriate empirical antibiotic therapy. However, it should also be appreciated that immunosuppressed recipients do not always produce a febrile response to infection.

MANAGEMENT OF CMV INFECTION AFTER LIVER TRANSPLANTATION

CMV infection is rarely associated with symptomatic illness in healthy hosts, but is a major cause of morbidity and mortality in transplant recipients; it is the single most common opportunistic infection after solid organ transplantation. In the absence of antiviral prophylaxis

Table 101.7 Infection in the intensive care unit

	BACTERIAL	VIRAL	FUNGAL	PROTOZOAL
AETIOLOGY	Wound Nosocomial pneumonia Line sepsis UTI Liver Biliary	HSV CMV EBV Varicella	*Candida* *Aspergillus* PCP *Cryptococcus*	Toxoplasmosis *Strongyloides*
TIMING	Any time	HSV in first few weeks CMV 3–10 weeks EBV from 4 weeks Varicella later All may be earlier in ALF or retransplantation	Usually after 4 weeks	After 3 weeks

the overall incidence of CMV infection after OLT ranges from 23 to 85%, with approximately 50% of those developing clinical disease. CMV infection most commonly occurs in the first 3 months after OLT, with a peak incidence in the third and fourth week. Infection may be asymptomatic or it may cause a spectrum of illness including fever, thrombocytopenia, neutropenia, pneumonia and hepatitis. The indirect effects of infection probably contribute more to the adverse effects on graft function than direct effects. CMV infection further immunosuppresses the recipient, leading to increased opportunistic fungal infection and also increased risk of Epstein–Barr virus (EBV) infection, which can go on to be associated with post-transplant lymphoproliferative disease (PTLD). CMV infection is also implicated in increased rejection. In those patients who proceed to transplant who are already receiving immunosuppressive agents, or in those with acute liver failure, CMV disease may present earlier in the clinical course.

The risk of CMV infection post-transplant is dependent on the serological status of both the donor and recipient; the highest risk is associated with donor positive/recipient negative. Proven prophylactic strategies in the high-risk groups include valganciclovir or ganciclovir for 3 months. Currently, intravenous ganciclovir remains the gold standard in the treatment of CMV disease. Therapy will be converted to oral ganciclovir to facilitate discharge from hospital and rehabilitation. There is no evidence to support specific immunoglobulin in addition, but it is frequently added in the management of CMV pneumonitis.[64]

MANAGEMENT OF VIRAL HEPATITIS

Hepatitis C (HCV)-related cirrhosis is the commonest indication for transplantation in both Europe and the USA. Post-transplant HCV viraemia is universal. Recurrent liver disease, with a more accelerated and aggressive course, is often observed; indeed, 20% are cirrhotic at 5 years.[67] Those with histological evidence of recurrence also have a greater incidence of acute rejection. Immunosuppression, especially with steroids, directly increases the HCV RNA serum load. Most post-transplant programmes therefore convert to single- or double-agent immunosuppression regimens as soon as possible.[68] Still to be fully elucidated is the role of antiviral therapy (interferon and ribavirin) in both the pre- and post-transplant period. Provisional data are optimistic, although it requires considerable workload and supportive drug therapy. It would not normally be undertaken in the intensive care setting. Theoretically, early antiviral therapy is attractive as viral load is low, immunosuppressive therapy has just started and acute rejection necessitating pulsed steroids is relatively common. However, risk of infection and thrombocytopenia often contraindicates antiviral therapy in the early postoperative period. Retransplantation for HCV recurrence has been shown to be a successful possibility should the transplanted liver begin to fail.[69]

Initial results of transplantation for hepatitis B infection (HBV) were discouraging, largely owing to recurrent disease with rapid and fatal progression. Passive immunoprophylaxis with hepatitis B immune globulin (HBIG) during and after transplant and the use of antiviral agents pre-transplant to suppress viral replication dramatically reduce re-infection rate. However, such therapy must be continued indefinitely following transplant to prevent disease recurrence. In respect of modulation of immunosuppression regimens, the comments made with respect to HCV are similarly applicable.

IMMUNOSUPPRESSION

As the field of transplantation evolves, new immunosuppressive regimens and drugs become available. For all combinations, however, there is a balance to be struck between the optimal prevention of rejection and the toxicity and unwanted effects of the drugs. These agents affect T-cell-dependent B-cell activation, targeting different sites in the T-cell activation cascade by inhibiting T-cell activation or causing T-cell depletion. The incidence of acute rejection rises at about 1 week

after OLT; it resembles a delayed-type hypersensitivity reaction, and immunosuppressive agents are highly effective at treating it. Chronic rejection occurs over months to years and is characterised by the 'vanishing bile-duct' syndrome; pathological mechanisms are poorly understood and immunosuppressant agents are largely ineffective.[58]

Currently, calcineurin inhibitors such as ciclosporin and tacrolimus, along with steroids, form the mainstay drugs after liver transplantation, certainly in the early stages. They have revolutionised the outcome of solid-organ transplantation, but both drugs are limited by their side-effects, predominantly nephro- and neurotoxicity, necessitating drug level monitoring. These manifestations of toxicity can be difficult in the management of post-transplant immunosuppression in patients who exhibited encephalopathy or renal dysfunction pre-transplant; the use of agents without nephrotoxic profiles may be considered in this context. It is usual to have an induction regimen beginning in the perioperative period; this usually involves a calcineurin inhibitor and steroids, which are administered in a high-dose taper regimen. With time after transplantation, the level of immunosuppression required decreases and drug doses may be reduced further. Cytotoxic drugs such as azathioprine or mycophenolate mofetil (MMF) may also allow further reduction of steroids and calcineurin inhibitors. The long-term effects of immunosuppression have to be considered but are less pertinent in the immediate postoperative period.

Another variation in the regimen is the introduction of antilymphocyte antibodies (ALA) for 10–14 days in order to delay the introduction of calcineurin inhibitors: this may be desirable in patients with impaired renal function. ALA interferes with lymphocyte function in several ways: enhanced removal of activated lymphocytes by the reticuloendothelial system, down-regulation of lymphocyte-binding cell surface receptors, with decreased lymphocyte activation and proliferation. Recently, monoclonal antibodies have been introduced (basiliximab). They bind to IL-2 receptors, which are only present on activated T-cells, and hence they have a more specific mode of action and favourable toxicity profile. The role of such agents, especially in those with renal dysfunction, is gaining greater recognition.

Sirolimus is a novel immunosuppressant that has been used extensively in renal transplantation and more recently in liver transplant recipients in whom the calcineurin inhibitors are contraindicated.[58] It resembles tacrolimus structurally, and binds to the same protein, but whereas ciclosporin and tacrolimus act by inhibiting *IL-2* gene transcription, sirolimus acts by blocking post-receptor signal transduction and IL-2-dependent proliferation. In addition to its immunosuppressive actions, sirolimus is also an antifungal and antiproliferative agent. Sirolimus lacks neuro- and nephrotoxicity. However, it can raise the intracellular concentrations of ciclosporin A and tacrolimus, indirectly potentiating their toxicity. Hyperlipidaemia has also been noted, although this may be a reflection of the often-higher-dose steroid regimens used in combination with sirolimus. Because of its antiproliferative effects, sirolimus can also cause thrombocytopenia, neutropenia and anaemia; there have also been concerns about its effects on wound healing. Sirolimus also requires therapeutic drug level monitoring, not only because serum concentrations have a high level of intra- and inter-individual variability, but also because there are significant interactions with drugs that use the cytochrome P-450 3A system. All immunosuppressive regimens should be tailored to individual patient needs and a balance struck between side-effects (short and long term) and risk of rejection.

RE-ADMISSION TO ICU/LATE COMPLICATIONS

The cause of re-admission to ICU after liver transplantation varies in relation to time after transplantation. Approximately 20% of recipients require re-admission, and this correlates with actuarial reduced patient and graft survival. In the period immediately after transplantation, cardiorespiratory failure is the commonest reason for re-admission, due to both fluid overload and infection. Indeed, an abnormal pre-discharge chest X-ray is predictive of re-admission, as is high central venous pressure and tachypnoea. Other predictors of re-admission are age, pre-transplant synthetic function, bilirubin, amount of intraoperative blood products and renal dysfunction. Graft dysfunction, severe sepsis and postoperative care of surgical complications are other important causes of readmission. Bleeding and biliary anastomotic leaks represent the commonest surgical causes for readmission.

LIVER TRANSPLANTATION FOR ACUTE LIVER FAILURE

Acute liver failure is a syndrome associated with an acute-onset coagulopathy, jaundice and encephalopathy; the causes are many and the syndrome is notable for its high morbidity and mortality. The acceptance of emergency liver transplantation in selected cases has revolutionised the clinical course, but outcome is sometimes disappointingly poor, often resulting from the rapid development of uncontrollable cerebral oedema, sepsis and multiorgan failure. There is also a short window of opportunity in listing these patients; despite highest priority listing they may receive 'marginal' organs or even ABO blood group incompatible organs. Early determination of prognosis and appropriate listing for transplant are clearly important. The King's College Hospital prognostic criteria for non-survival among patients with acute liver failure is a tool used to identify those at high risk while sparing those in whom

Table 101.8 King's College Hospital prognostic criteria for non-survival among patients with acute liver failure

PARACETAMOL INDUCED	NON-PARACETAMOL INDUCED
pH<7.3 (irrespective of grade of encephalopathy), following volume resuscitation and >24 hours post ingestion, *or*	PT>100 seconds (INR>6.5) irrespective of grade of encephalopathy, *or* pH<7.3 following volume resuscitation, *or*
PT>100 seconds (INR>6.5) *and* creatinine >300 µmol/L in patients with grade III–IV encephalopathy, occurring within a 24-hour timeframe	Any three of the following variables (in association with encephalopathy): Age <10 years or >40 years Aetiology: non-A, non-B or drug induced Jaundice to encephalopathy >7 days PT>50 seconds (INR>3.5) Serum bilirubin >300 µmol/L

spontaneous recovery will otherwise occur. It has been validated in both Europe and the USA (**Table 101.8**). Several advances in the supportive management of these patients have occurred since the original criteria were developed, but their prognostic value holds true.

PAEDIATRIC LIVER TRANSPLANTATION

OLT is the treatment of choice for children with end-stage liver disease. Cholestatic disorders make up the largest indication for transplantation, with extrahepatic biliary atresia plus or minus previous Kasai porto-enterostomy accounting for over 50% of paediatric transplants. Metabolic diseases and primary hepatic tumours are also common indications. As in adult recipients, multisystem effects of end-stage liver disease are common, and the occurrence of liver disease as part of a congenital syndrome (e.g. Alagille's) may warrant invasive preoperative evaluation of extrahepatic manifestation. Scarce availability of paediatric donors has driven innovations such as reduced size grafts, split-liver techniques and living donor programmes, which have all contributed to expand the pool of available donors and reduce the mortality for those children waiting for suitable organs.

One of the biggest problems associated with paediatric transplantation is the relatively high incidence of vascular complications such as hepatic artery thrombosis, portal vein thrombosis and venous outflow obstruction. Risk factors for these conditions include fulminant hepatic failure, long operation time, donor/recipient age and weight discrepancies, young recipient age, low recipient weight and arterial reconstruction techniques. In order to minimise these often devastating complications, strategies to minimise the risk include delayed primary closure of the abdominal wall, maintaining the haematocrit at 22–25% to ensure laminar flow, and avoidance of platelets and blood components combined with considered use of anticoagulants. Associated cardiac, pulmonary or renal abnormalities observed in some paediatric syndromes with liver disease may require particular attention and management such as the pulmonary stenosis seen in association with Alagille's.

Ten-year survival rates of 74 (age 12–17 years) – 84% (age 1–5 years) has brought about a new set of challenges relating to complications and management of long-term immunosuppression. The concept of tolerance-inducing immunosuppressive regimens has spurned a number of studies investigating this phenomenon.[70]

Heart and lung transplantation

Peter S Macdonald and Paul C Jansz

The first human-to-human heart transplant was performed in 1967 by Christiaan Barnard at Groote Schuur Hospital in South Africa. The donor heart functioned well immediately post-transplant and the patient survived for 18 days before dying from pneumonia complicating his immunosuppressive therapy. There followed an initial wave of surgical enthusiasm with multiple centres around the world commencing heart transplant programmes. Initial results were poor, however, with high early mortality rates and few long-term survivors. Many institutions abandoned the procedure and only a handful of heart transplant programmes persisted throughout the 1970s. The discovery of ciclosporin as an effective immunosuppressive agent and its introduction into clinical transplantation in the late 1970s led to renewed interest in heart transplantation with a rapid growth in transplant activity throughout the 1980s. Since then more than 100 000 heart transplants have been reported to the Registry of the International Society for Heart & Lung Transplantation (ISHLT).[1] Currently, it is estimated that more than 5000 transplants are performed each year in over 300 countries.[1] The survival rate after heart transplantation has improved steadily over the last two decades and currently approaches 90% at 1 year, 80% at 5 years and 60% at 10 years. Median survival is 11 years. Heart transplantation is now well established as the most effective treatment available for end-stage heart failure.

Human lung transplantation also commenced in the 1960s but as with heart transplantation early results were dismal and the procedure was largely abandoned until the 1980s. The first successful heart–lung transplant was performed at Stanford University Medical Center in 1981. During the next decade single-lung and bilateral-lung transplantation emerged as viable procedures for patients with end-stage lung disease. More than 40 000 lung transplants have been reported to the ISHLT registry and currently more than 3000 lung transplants are performed annually around the world.[2] Post-transplant survival although not as good as for other organs has improved steadily. In the most recent publication of the ISHLT registry median post-transplant survival was 5.5 years with 80% survival at 1 year, 53% at 5 years and 30% at 10 years.[2] Whereas heart transplant activity has plateaued in the last decade, lung transplant activity has been increasing steadily.[2]

Heart and lung transplantation are limited by donor organ availability. With rare exceptions, hearts and lungs donated for transplantation come from deceased persons. Historically, the vast majority of deceased donors for both heart and lung transplantation had undergone brain death (DBD). More recently, donation after circulatory death (DCD) has re-emerged as an important source of donor lungs as well as abdominal organs and in some cardiopulmonary transplant programmes up to one-third of lung transplants are performed from DCD donors.[3]

Virtually all of the improvement in heart and lung transplant survival over the last 20 years has been during the first few months after transplantation.[1,2] The improvement in survival can be explained by a number of factors including advances in immunosuppressive therapy with fewer deaths due to uncontrollable rejection or infection and better patient selection by excluding patients who are too sick to recover from the stresses of transplant surgery. Nevertheless, the first few days and weeks after transplantation is still a period of high mortality risk for transplant recipients, owing mainly to the complications of primary graft failure (PGF) or overwhelming infection.

THE POTENTIAL HEART DONOR

Of all organs retrieved from deceased donors for transplantation, the heart is the one most susceptible to the multiple insults that occur during brain death and the subsequent events that occur during donor organ retrieval and transplantation. Studies involving repeated echocardiographic examination of the brain-dead donor have revealed that left ventricular systolic dysfunction is common after brain death and that it often improves together with haemodynamic status after a period of aggressive donor management.[4]

In addition to its susceptibility to the adverse consequences of brain death, the heart is the donor organ with the least tolerability to the obligatory ischaemia reperfusion injury (IRI) that occurs during organ retrieval and implantation. Data from the ISHLT Registry indicates that, as the donor heart ischaemic time (the time from cross-clamp of the aorta in the donor to

release of the aortic cross-clamp in the recipient) increases beyond 3 hours, there is a progressive increase in the mortality rate at 1 year post-transplant.[1] Donor heart ischaemic times in excess of 6 hours are associated with a 70% increase in the risk of death at 1 year post-heart transplantation.[1] Consequently, when coordinating the retrieval of donor organs, every effort is made to minimise the ischaemic time for the donor heart. In addition there is substantial evidence from large observational studies that hearts from older donors are more susceptible to IRI.[1,5] For this reason, the upper age limit for donor hearts in many programmes is restricted to a donor age less than 60 years. Even with this donor age restriction, hearts are still retrieved from only a minority of brain dead donors. In most jurisdictions hearts are retrieved from only about 30% of deceased donors.

DONOR ELIGIBILITY CRITERIA

Donor eligibility criteria vary between jurisdictions. Those that are currently utilised in Australia and New Zealand are summarised in **Table 102.1**.[6] As shown in the table, donors are subdivided into standard criteria and extended criteria donors based on a range of donor characteristics that if present are associated with an increased risk of graft failure and lower survival after transplantation. With rare exceptions, donor hearts are retrieved from brain-dead donors. There have been isolated case reports and small series of successful heart transplantation from DCD donors.[7] Given the rapid increase in organ donation from DCD donors in the last few years, there has been renewed interest in the utilisation of hearts from DCD donors for heart transplantation, but at present this remains an experimental activity. Echocardiographic assessment of the donor heart is recommended in all cases. Donor heart dysfunction does not necessarily imply pre-existing disease, but is associated with an increased risk of primary graft failure.[8] In donors with suspected coronary artery disease, coronary angiography is recommended if available.

DONOR MANAGEMENT

Although there has been considerable interest in donor management strategies aimed at optimising the quality of the donor heart, the most effective management strategy for the brain-dead potential organ donor in the period between determination of brain death and organ procurement for transplantation has not been established. Routine management of the potential cardiac donor after determination of brain death includes maintenance of ventilation, fluid and electrolyte balance. Central venous, arterial blood pressure and urinary catheters are recommended to monitor haemodynamic stability and ongoing fluid loss. Loss of autonomic tone and the onset of diabetes insipidus may result in severe haemodynamic instability and potentially large urinary volume losses. The majority of potential cardiac donors require a vasopressor agent to maintain arterial blood pressure and either intravenous vasopressin or subcutaneous DDAVP to correct diabetes insipidus. If donors fail to respond to these measures then more aggressive resuscitation including the use of a Swan–Ganz catheterisation to monitor central haemodynamics and combined hormonal administration have been recommended.[9]

Registry studies indicate that inotropic/vasopressor agents are administered to more than 90% of donors with norepinephrine (noradrenaline) being the most commonly administered agent.[10] Observational studies have suggested that the use of catecholamines may have divergent effects on different donor organs. For example, in one large retrospective analysis, Schnuelle and colleagues reported that the administration of

Table 102.1 Standard versus extended criteria for donor hearts

DONOR PARAMETER	STANDARD CRITERIA	EXTENDED CRITERIA (MARGINAL)
Age	<50 years	>50 years
Donor cardiac history	Nil	Pre-existing disease
Donor co-morbidities	Absent	Hepatitis B, C
Echocardiography*	Normal	Global dysfunction (LVEF<50%) Major regional wall motion abnormality Left ventricular hypertrophy (LV wall >13 mm)
Coronary angiography*	Normal or non-occlusive disease	Occlusive coronary artery disease
Haemodynamic status	Stable	Unstable with high CVP (and/or PAWP) and low BP
Inotropic support	Low	High (>0.2 μg/kg/min of norepinephrine or equivalent)
Ischaemic time	<6 hours	>6 hours

*Severe abnormalities will generally result in non-use of the organ.

catecholamines to multi-organ donors was associated with improved post-transplant outcomes for recipients of renal transplants, but worse outcomes for recipients of cardiac transplants.[11] In a subsequent large prospective randomised placebo-controlled trial of low-dose dopamine (4 μg/kg/min) in potential multi-organ donors, the same investigators found that dopamine administration to donors (who were already receiving norepinephrine in doses of less than 0.4 μg/kg/min) resulted in a reduced requirement for post-transplant dialysis in both renal transplant recipients and heart transplant recipients from the same donor.[12] Moreover, overall survival was improved in the heart transplant recipients.[13]

Vasopressin is another vasopressor agent that has been administered to the brain-dead donor often as part of a multihormonal cocktail usually with high-dose steroids and thyroid hormone.[14] Use of other hormonal therapies, particularly thyroid hormone administration, is controversial. In a recent systematic review, Macdonald and co-authors identified 16 separate case series and 7 prospective randomised controlled trials of thyroid hormone administration to brain-dead potential organ donors.[15] Whereas all case series reported a beneficial effect of thyroid hormone administration on a range of outcomes, including donor haemodynamic stability and donor heart utilisation, none of the randomised controlled trials reported any benefit from thyroid hormone administration. Despite this controversy, thyroid hormone administration in conjunction with other hormonal therapies has been recommended as part of an aggressive management protocol for the potential cardiothoracic donor and has been incorporated into the UNOS Critical Pathway for the organ donor.[9]

DONOR HEART PRESERVATION

The most common method of donor heart preservation involves cardioplegia with a cold hyperkalaemic crystalloid solution then cold static storage in a preservation solution in an ice chest during transport between donor and recipient hospitals. There are multiple preservation solutions that are in use, reflecting a lack of consensus regarding the optimal composition of these solutions.[16] All provide good preservation for up to 3 hours, but beyond this time there is a steady increase in the rate of PGF and mortality after heart transplantation. This has led to a renewed interest in the use of ex vivo machine perfusion devices to transport hearts between donor and recipient hospitals. These devices provide oxygen to the donor heart and restore aerobic metabolism during transport, thereby minimising the ischaemic insult to the donor heart. Small clinical trials have been conducted with these devices to date and it remains to be seen whether they improve the quality of the donor heart and broaden the pool of potential heart donors.

THE POTENTIAL LUNG DONOR

Experience has demonstrated that the donor lung has a greater tolerability to the adverse sequelae of brain death and subsequent insults associated with lung retrieval and transplantation than was initially thought to be the case. In particular, the tolerability of the donor lung to ischaemia reperfusion injury during retrieval and transplantation is better than that of the heart. Donor lung function appears to be less adversely affected by age than does donor heart function and in some jurisdictions donors up to age 70 are considered for lung donation.[6] In addition, the lungs of DCD donors have been found to be relatively resistant, compared with all other donor organs, to the warm ischaemia associated with withdrawal of life support. DCD donors have now become a major source of donor lungs contributing up to 30% of lung donors in some programmes.[3] For all these reasons, the numbers of lung transplants has been increasing both in absolute terms and as a proportion of all deceased donors.

DONOR ELIGIBILITY CRITERIA

As with heart transplantation, donor eligibility criteria for lungs vary between jurisdictions and there are separate categories for standard criteria and extended criteria donors (**Table 102.2**).[17,18] Although there have been concerns that the use of extended-criteria lung donors will lead to increased rates of early graft failure and death after lung transplantation, for some donor characteristics such as donor age, donor Pa_{O_2} or mode of death (DCD versus DBD) this has been found not to be the case.[17,19] Moreover, the increased risk associated with the use of lungs from donors with characteristics

Table 102.2 Standard versus extended criteria for donor lungs

DONOR PARAMETER	STANDARD CRITERIA	EXTENDED CRITERIA (MARGINAL)
Age	<55 years	>55 years
Smoking history	<20 pack years	>20 pack years
Chest trauma	Absent	Present
Aspiration	Absent	Present
Chest X-ray	Clear	Abnormal
Arterial blood gases	Pa_{O_2}>300 mmHg (40 kPa) on Fi_{O_2} of 100%	Pa_{O_2}<300 mmHg (40 kPa) on Fi_{O_2} of 100%
Sputum	Nil or minimal	Purulent, documented infection
Bronchoscopy	Clear or minimal secretions	Purulent secretions

associated with increased post-transplant mortality (e.g. donor smoking history) needs to be balanced against the risk of death on the waiting list.[20]

DONOR MANAGEMENT

A major challenge for the intensive care specialist caring for a potential multi-organ donor is balancing the haemodynamic goals that are optimal for one organ versus those of another. Whereas aggressive diuresis and fluid restriction may help to optimise lung gas exchange, the resultant volume depletion is likely to reduce perfusion to intra-abdominal organs. The main goals of haemodynamic management are to maintain normal central filling pressures and to use the lowest doses of vasopressor agents needed to maintain a mean arterial pressure above 70 mmHg (9.31 kPa).

In recent years there has been a significant shift in the ventilation strategy for brain-dead potential lung donors from a conventional (tidal volume 10–12 mL/kg and 3–5 cm H_2O PEEP) to a lung-protective strategy (6–8 mL/kg tidal volume and 8–10 cm H_2O PEEP). Other features of the lung-protective ventilation strategy are apnoea tests performed during continuous positive airway pressure and maintenance of a closed circuit during airway suction.[21] Use of a lung-protective ventilation strategy compared with a conventional ventilation strategy led to a doubling of the number of suitable lung donors in one large multicentre randomised trial.[21] There has also been interest in the administration of inhaled β_2-agonists to potential lung donors based on experimental evidence of improved donor lung quality and reduced primary graft dysfunction,[22] although preliminary results of a large study of over 500 potential lung donors were discouraging.

The other important aspect of management of the potential lung donor is donor bronchoscopy, particularly in donors with abnormal CXR findings. This is often performed by the lung retrieval team on arrival at the donor hospital. Bronchoscopy facilitates identification of any pathology that would contraindicate transplantation, clearance of inspissated secretions causing atelectasis and lavage sampling of the lower respiratory tract for potential pathogens that might precipitate infection in the recipient.

The very first human lung transplant like the very first human heart transplant was performed from a DCD donor. Interest in the use of lungs from DCD donors was reignited by Steen and colleagues in 2001 who also used an ex vivo lung perfusion system to assess donor lung quality.[23] Since then DCD lung donation has emerged as a major source of donor lungs for transplantation.[24] Indeed, the lung appears to demonstrate greater tolerability to ischaemia in this setting than any other organ so that warm ischaemic times of up to 90 minutes after withdrawal of life support have been tolerated prior to lung retrieval and successful lung transplantation.

DONOR LUNG PRESERVATION

As with heart preservation, the major method of donor lung preservation has been administration of a cold pneumoplegic solution followed by static storage in a lung preservation solution. Perfadex, a normokalaemic colloid solution based on dextran 40, has emerged as the favoured lung storage solution in most lung transplant programmes. It has been found to provide effective donor lung preservation from both DBD and DCD donors.

A major advance in donor lung preservation has been the use of ex vivo lung preservation (EVLP) devices. This concept was first advanced by Steen and colleagues[23,25] and later developed by Cypel and co-workers, who reported that EVLP could be used not only to prevent deterioration in lung function but also to restore function in lungs from extended criteria donors.[26]

HEART TRANSPLANTATION

SELECTION OF PATIENTS FOR HEART TRANSPLANTATION

Eligibility criteria for heart transplantation have been extensively reviewed elsewhere and will be discussed only briefly.[27,28] Heart transplantation is restricted to patients with end-stage heart disease who have exhausted all alternative therapies. Most patients have long-standing and intractable heart failure due to either ischaemic heart disease or some form of cardiomyopathy.[1] A substantial proportion of these patients require long-term mechanical circulatory support (so-called bridge to transplant) and in most jurisdictions between 30% and 50% of waiting-list patients are on mechanical circulatory support.[1] There has been a dramatic evolution in the design of mechanical devices to support the circulation – from large pulsatile pumps to small continuous flow devices that can be implanted in much smaller recipients and have proven to be far more durable.[29] Two-year survival rates for persons supported on continuous flow devices are now better than 80%.[30] Patients on long-term ventricular assist device (VAD) support can generally be managed as outpatients and undergo cardiac rehabilitation to optimise their physical condition prior to transplant surgery. VAD support has also been used in patients who are otherwise marginal candidates for heart transplantation owing to factors such as renal impairment and pulmonary hypertension (so-called bridge to decision). Long-term VAD support has been associated with reversal of these co-morbidities in several case series.[31,32]

A small proportion of patients who require consideration for heart transplantation present acutely in cardiogenic shock following acute myocardial infarction, cardiac surgery (post-cardiotomy syndrome) or in association with myocarditis. Short-term survival of these critically ill patients is usually dependent on acute

mechanical circulatory support (e.g. with veno-arterial extracorporeal membrane oxygenation (VA ECMO)). Following stabilisation of vital organ function and establishment that the heart will not recover, these patients will usually be transitioned to a VAD designed for long-term support. There has been considerable interest in the use of mechanical circulatory support as a 'bridge to recovery'. This is most commonly observed when the indication for support is acute fulminant myocarditis. Spontaneous recovery of cardiomyopathic hearts following long-term mechanical support has also been reported, although this appears to be the exception rather than the rule.

HEART TRANSPLANT SURGERY

Heart transplantation can be performed either as an orthotopic or heterotopic procedure. The vast majority of heart transplants are performed orthotopically by excising the native heart and implanting the donor heart in its place. The original surgical technique described by Shumway and Lower[33] is still widely performed. This technique involves anastomosis of the left and right donor atria to the back walls of the corresponding recipient atria containing the central connections of the vena cava and pulmonary veins. An alternative surgical technique for orthotopic heart transplantation involves bicaval anastomosis. The right atrial bicaval anastamosis can be performed alone or in conjunction with anastomosis at the level of the pulmonary veins rather than at the level of the left atrium. The proposed advantages of this technique include better preservation of atrial anatomy and function with reduced risk of atrial thrombosis, atrial arrhythmias and atrioventricular valve regurgitation during long-term follow-up. Surgical series comparing these two approaches, however, suggest that long-term clinical outcomes are similar.

Heterotopic heart transplantation refers to the technique in which the native heart is retained and the donor heart is implanted 'in parallel'. First described by Barnard and colleagues,[34,35] the operation is achieved by anastomosing the left and right atria 'back to back' and then connecting the donor pulmonary artery and aorta to the recipient pulmonary artery and aorta with end-to-side anastomoses. A synthetic pulmonary artery graft is usually required to enable anastomosis between donor and recipient pulmonary arteries. Heterotopic transplantation is now rarely performed. The most common indication is for recipients with fixed pulmonary hypertension. In this setting an allograft that is used to operating against normal pulmonary pressures would fail once transplanted into an environment of pulmonary hypertension; however, in a heterotopic transplant the trained right ventricle of the recipient continues to maintain flow through the pulmonary vascular bed while the heterotopic heart functions primarily as a left ventricular assist. Permanent pacing wires, defibrillator wires and the corresponding systems are removed at the time of the transplant. During the implant the heart is no longer afforded the protection of hypothermia. This critical period of warm ischaemia must be kept to a minimum. To assist in the protection and resuscitation if the heart during this period a dose of blood cardioplegia is administered after the atrial anastomoses are completed.

Once the atrial, pulmonary artery and aortic connections are completed vents are placed in the left ventricle and the aorta, the heart is de-aired and the cross-clamp released. Temporary pacing wires are placed onto the heart and the heart is allowed a period of reperfusion whilst on cardiopulmonary bypass. The duration of the unloaded reperfusion varies and is related to the ischaemic time. A heart that has endured an ischaemic time (from cross-clamp in the donor to reperfusion in the recipient) of 4 hours may be given up to 1 hour of reperfusion before commencing separation from cardiopulmonary bypass and allowing the heart to work. Separation from cardiopulmonary bypass and the completion of the procedure needs to proceed carefully as the transplanted heart, in particular the right ventricle, is prone to acute failure.

POST-TRANSPLANT MANAGEMENT

IMMEDIATE POST-TRANSPLANT CARE AND MONITORING

As with routine cardiac surgical cases, heart transplant recipients are transferred from the operating room to the ICU bed still anaesthetised, intubated and ventilated. In the stable uncomplicated case after transfer to the ICU, sedation will be weaned and the patient extubated when sufficiently conscious, usually after 6–8 hours. Routine monitoring includes an ECG, arterial line, Swan–Ganz catheter and urinary catheter. In some centres, separate left atrial and CVP lines have been used instead of the Swan–Ganz catheter; however, the latter has the advantage of providing a direct measure of the pulmonary vascular resistance, which if elevated may cause acute right heart failure of the 'untrained' donor heart. Pericardial, mediastinal and one or more pleural drains (depending on the complexity of the transplant surgery) will be in place.

PHYSIOLOGY OF THE TRANSPLANTED HEART

The cardiac rhythm of the transplanted heart in the immediate post-transplant period is highly variable. Although there may be early establishment of sinus rhythm at a rate commensurate with the denervated state of the heart, usually the heart is profoundly bradycardic during the first few days after transplantation. Typically the sinus rate increases steadily over the first 1–2 weeks post-transplant and eventually stabilises at a resting rate between 90 and 100 per minute. Drugs that act by augmenting or inhibiting vagal efferent

activity (e.g. digoxin, atropine) will have no effect on the heart rate of the transplanted heart. The transplanted heart is often 'stunned' by the reperfusion injury that occurs in the first 24 hours after transplantation. During this period the heart often demonstrates diastolic dysfunction with a restrictive filling pattern, which may persist for days after transplant surgery. Persistence of diastolic dysfunction beyond the first week post-transplant suggests the development of acute rejection.

CARDIAC RHYTHM AND PACING

A–V sequential pacing with temporary pacing wires is routine in the immediate post-transplant period. Filling pressures of 10–15 mmHg (1.33–2 kPa) may be required to ensure adequate diastolic filling and AV sequential pacing at rates up to 110 per minute may be required to maintain a normal cardiac output and stable arterial pressure. Pacing is gradually weaned over the first week post-transplant. During this period the sinus rhythm of the transplanted heart usually increases steadily. Temporary pacing is suspended when a stable sinus rhythm above 60 per minute is established, usually within the first week after transplantation when the heart has also recovered from its initial 'stunning'. Administration of amiodarone to the recipient *prior to* transplantation may delay sinus node recovery. Between 5 and 10% of transplanted hearts remain profoundly bradycardic or develop tachy–brady syndrome (possibly due to sinus node injury during recovery of the donor heart) and require implantation of a permanent pacemaker. Usually 3 weeks are allowed for recovery of sinus rhythm. Oral beta agonists have been used to accelerate sinus node recovery, but it is unclear whether they are effective or reduce the need for permanent pacing.

Tachyarrhythmias are uncommon after transplantation. Atrial fibrillation is probably less common than after other forms of cardiac surgery possibly owing to better preservation of atrial myocardium. Atrial flutter occurring beyond the first week post-transplant is suggestive of acute rejection and should prompt endomyocardial biopsy. If pacing wires are still present they can be used to attempt atrial overdrive pacing (AOD). Alternatively AOD pacing can be performed at the completion of the biopsy procedure. Ventricular tachyarrhythmias are very uncommon and usually observed in the setting of severe acute graft dysfunction and primary graft failure.

INOTROPIC AGENTS

Isoproterenol (isoprenaline) has been used traditionally in the immediate post-transplant ICU phase based on its chronotropic, inotropic and pulmonary vasodilator properties. There have been no large-scale controlled trials comparing different inotropic and chronotropic drugs in the immediate post-transplant period, however, so it is unclear whether these properties of isoproterenol make it any more effective than alternative i.v. inotropic agents such as dobutamine and epinephrine (adrenaline). Epinephrine is often co-administered if the patient is hypotensive with mean arterial pressures below 70 mmHg (9.31 kPa). Thyroid hormone administration to the heart transplant recipient has been advocated by some authors but, as with its use in the donor, its administration to the recipient after heart transplantation is controversial. In the routine case, inotropic and vasopressor support can usually be weaned within the first 48–72 hours as the donor heart recovers.

ARTERIAL BLOOD PRESSURE CONTROL

Prior to heart transplant, the recipient's arterial circulation in many cases has adapted to chronic systemic hypotension with systolic blood pressures in the range 80–90 mmHg (10.64–11.97 kPa). Replacement of an end-stage failing heart with a healthy donor heart often leads to a rapid increase in arterial blood pressure in the recipient as the donor heart regains normal function over the first few days post-transplant. This may be further exacerbated by the introduction of ciclosporin, which causes both renal and systemic vasoconstriction. Systolic blood pressures in excess of 140 mmHg (18.62 kPa) in the first weeks after heart transplantation may result in hypertensive encephalopathy, which may manifest as headache, drowsiness and seizures. Strict control of blood pressure, initially with intravenous vasodilators such as glyceryl trinitrate then with oral agents, may be required to prevent dangerous increases in arterial blood pressure during this early postoperative phase.

IMMUNOSUPPRESSION

Maintenance immunosuppression initially involves the administration of three drugs in combination: high-dose corticosteroids, an antimetabolite (mycophenolate mofetil (MMF) or azathioprine) and a calcineurin inhibitor (CNI, ciclosporin or tacrolimus). Approximately 50% of transplant units also use *induction* therapy, either a T-cell cytolytic agent (e.g. antithymocyte globulin) or an antibody that specifically blocks the activated IL-2 receptor (e.g. basiliximab).[1] The T-cell cytolytic agents are more potent immunosuppressive agents but are also associated with more side-effects related to the acute destruction of large numbers of T cells in the circulation – so-called cytokine release syndrome. Their use is associated with an increased risk of viral and fungal infections as well as later development of post-transplant lymphoproliferative disease (PTLD). They may be administered as a fixed daily dose or adjusted according to the daily T-cell count. The IL-2R inhibitors have a much better side-effect profile and their use is not associated with any increased risk of infection or PTLD. Some transplant units use induction agents routinely, whereas others restrict their use to specific situations (e.g. where there is a delay in commencement of

the calcineurin inhibitor, usually because of persistent renal dysfunction in the recipient). Other transplant units use induction agents rarely if at all. Induction agents are usually commenced intraoperatively prior to reperfusion of the transplanted heart. Postoperative administration varies according to the agent used.

Dosing schedules of maintenance immunosuppressive drugs vary considerably between transplant units, although there is little evidence to support one approach over another. Steroids are initially administered intravenously in high doses, typically methylprednisolone 500 mg i.v. in the anaesthetic bay and again prior to reperfusion. A further 3 doses of 125 mg methylprednisolone are administered over the first 24 hours post-transplant, after which the recipient will commence a tapering dose of oral prednisolone starting at 1 mg/kg/day tapering to approximately 0.2 mg/kg/day by the 3rd week post-transplantation. MMF (or azathioprine) is administered with the premed then continued at 1.5 g b.d. either i.v. or orally. Ciclosporin or tacrolimus dosing is more variable. Some units administer the CNI preoperatively provided the recipient has normal renal function. Other units delay administration until after surgery when any acute perioperative renal dysfunction has resolved. Units also vary in their approach to CNI dosing and MMF dosing. Some use fixed dosing whereas others use therapeutic drug monitoring, adjusting the dose to meet target blood levels.

INFECTION PROPHYLAXIS

With currently used immunosuppressive drug protocols, the risk of infection is relatively low. Routine precautions including hand washing are applied as for standard ICU patients; however, patient isolation and barrier nursing are generally not required unless the patient is already colonised with multiresistant organisms.

Prophylactic antibiotic therapy is routine. A cephalosporin administered intravenously over the first 24 hours is routine; however, the choice of antibiotic may vary if the recipient is known to be colonised with one or more multiresistant organisms. *Pneumocystis* prophylaxis in the form of oral co-trimoxazole is commenced in the first week post-transplantation and continued indefinitely. Nystatin oral solution to prevent oropharyngeal candidiasis is also administered for the first 2 weeks post-transplant. Prophylaxis against other fungi particularly *Aspergillus* varies between units and may depend on local resistance patterns. Inhaled amphotericin for the first week followed by oral itraconazole for 3 months is one approach. In the event of a CMV mismatch (CMV-positive donor with CMV-negative recipient) oral valganciclovir is administered for the first 3 months post-transplant. Some units also administer valganciclovir to CMV-positive recipients.

Other routine drugs administered in the immediate post-transplant period include an insulin infusion as required to control hyperglycaemia, which is common following administration of high-dose steroids, proton pump inhibitors to prevent peptic ulceration and a statin. A typical post-transplant drug treatment protocol is shown in **Table 102.3**.

COMPLICATIONS

PRIMARY GRAFT FAILURE (PGF)

PGF is a syndrome in which the transplanted heart fails to meet the circulatory requirements of the recipient in the immediate post-transplant period as a consequence of either single or biventricular dysfunction. It is manifested as hypotension and low cardiac output in the presence of adequate filling pressures.[36] In most instances, it is likely to result from a multifactorial process with contributing elements from the donor, recipient and the transplant process.[8] Primary graft failure is the most feared early complication after heart transplantation and accounts for approximately 40% of all deaths within the first month.[1] The reported incidence of PGF after heart transplantation varies widely between studies with estimates ranging between 2.3 and 26%.[8] Most of the variability can be attributed to inconsistent definitions of PGF used by different authors. When PGF has been defined as the need for high-dose inotropes or mechanical assist devices in the immediate post-transplant period, most investigators have reported incidence rates of 10–20% or higher. Suggested diagnostic criteria for primary graft failure are listed in **Table 102.4**. Recognised risk factors for PGF are listed in **Table 102.5**.

Management of PGF depends on the severity and the mechanism of graft failure. In cases of selective or predominant right ventricular (RV) failure, pre-existing pulmonary hypertension (with or without acute exacerbation following cardiopulmonary bypass) is usually the cause. Selective pulmonary vasodilators such as inhaled nitric oxide or inhaled prostacyclin may provide sufficient RV unloading to restore cardiac output: however, the impact of these therapies on overall outcome is uncertain.[38–40] In severe cases implantation of an acute right ventricular assist device (RVAD) may be required. Longer-acting agents such as oral sildenafil may be required to allow weaning of nitric oxide and RVAD support in such cases.[41] In severe cases of left or bi-ventricular failure, early institution of total mechanical circulatory support is essential to avoid multi-organ failure.[42,43] A number of acute mechanical support options are available but the most widely used device is VA ECMO, which can be deployed by either peripheral or central cannulation.[42,43] Total circulatory support may be required for 7 days or longer.

INFECTIONS

Infections encountered in heart transplant recipients during the ICU phase of management are similar to those affecting routine cardiac surgical cases. Risk

Table 102.3 Perioperative heart and lung transplant drug treatment protocols currently utilised in the Heart and Lung Transplant Unit at St Vincent's Hospital, Sydney

AREA	HEART	LUNG
Preoperative on ward	Mycophenolate mofetil 1.5 g p.o.	Azathioprine 3 mg/kg p.o. Ciclosporin capsules p.o. 2 mg/kg if creatinine ≤ 120 µmol/L 1 mg/kg if creatinine = 130 µmol/L Omit if creatinine > 130 µmol/L (CF patients must take pancreatic enzymes as for 'snack' with oral ciclosporin capsules)
In anaesthetic bay	Basiliximab 20 mg i.v.: if creatinine >120 µmol/L on night of transplant, or previously recorded creatinine >120 µmol/L, or LVAD, BiVAD or TAH (Give second dose of 20 mg i.v. on day 4) Vitamin K 10 mg i.v.: if on warfarin Methylprednisolone 500 mg i.v. Ganciclovir 5 mg/kg i.v.: if CMV mismatch (D+/R–). Cefazolin 500 mg	Methylprednisolone 500 mg i.v. Ganciclovir 5 mg/kg i.v.: if CMV mismatch Cefotaxime 1g i.v.; however, antibiotics based on donor and recipient micro, consult respiratory physician
In theatre off bypass	Methylprednisolone 500 mg i.v. Cefazolin 500 mg i.v.	Methylprednisolone 500 mg i.v. Cefotaxime 1 g i.v.; however, antibiotics often based on donor and recipient micro, consult respiratory physician
ICU or ward	IMMUNOSUPPRESSION	IMMUNOSUPPRESSION
	DAY 1	
	Tacrolimus 0.5 mg p.o. or via nasogastric tube: if Cr < 140 µmol/L: give test dose or, if unable to commence oral therapy, commence infusion at 0.015 mg/kg/day i.v. given as continuous infusion over 24 h If Cr > 140 µmol/L: hold tacrolimus until creatinine <140 µmol/L Methylprednisolone 125 mg i.v. q. 8 h × 3 doses Myocphenolate mofetil 1 g i.v./p.o. b.d. *DAY 2 ONWARDS* Methylprednisolone 40 mg i.v. b.d. × 2 doses, *then* Prednisolone 0.6 mg/kg/day p.o. in 2 divided doses until 2 weeks post-transplant then wean by 0.1 mg/kg/day each week until complete withdrawal Mycophenolate mofetil 1 g i.v./p.o. b.d. Tacrolimus capsules p.o. b.d. as charted (titrate to target trough level of 8–12 µg/L by day 7) Basiliximab 20 mg i.v. on day 4 – *if given as induction.*	Ciclosporin 1 mg/kg i.v. as continuous infusion while intubated, increasing to 2 mg/kg depending on first steady state level (within 24–48 hours post-transplant). Initial target steady-state level = 400–450 µg/L Ciclosporin p.o. b.d. once extubated (NB: p.o. dose is approximately 3 times the i.v. dose) CF patients: ciclosporin p.o. t.d.s. given with pancreatic enzymes, dose as for 'snack' Azathioprine 2 mg/kg i.v./p.o. nocte Methylprednisolone 125 mg i.v. q. 8 h x 3 doses, *then* Prednisolone 1 mg/kg/day p.o. in 2 divided doses, tapering by 5 mg every second day to a single daily dose of 0.2 mg/kg (until first transbronchial biopsy)
	BACTERIAL PROPHYLAXIS	BACTERIAL PROPHYLAXIS
	Cefazolin 1 g i.v. q. 8 h × 3 doses	Cefotaxime 1 g i.v. t.d.s. for 5 days – (may vary according to cultures) Roxithromycin 300 mg p.o. nocte – *Chlamydia* management Co-trimoxazole 800 mg/160 mg p.o. (Bactrim DS®), 1 tablet mane on Mondays and Fridays only

Table 102.4 Suggested diagnostic criteria for primary graft failure after heart transplantation

PRESENCE OF	EVIDENCED BY
Ventricular systolic dysfunction – left, right or biventricular dysfunction	Echocardiographic evidence of dysfunction
Cardiogenic shock lasting more than 1 hour	Low systolic blood pressure <90 mmHg (11.97 kPa) *and/or* Low cardiac output – <2 L/min/m^2 despite adequate intracardiac filling pressures – CVP>15 mmHg (2 kPa) and/or PAWP>20 mmHg (2.66 kPa)
Circulatory support	Use of ≥2 inotropic agents/vasopressors including high-dose epinephrine or norepinephrine *and/or* Use of a mechanical assist device – IABP, ECMO, VAD
Appropriate time frame	Onset <24 hours post-transplantation
Exclusion of secondary causes of PGF	e.g. cardiac tamponade, hyperacute rejection

Table 102.5 Recognised risk factors for primary graft failure after heart transplantation

DONOR FACTORS	RECIPIENT FACTORS	PROCEDURAL FACTORS
Age >30 years	Age >60 years	Ischaemic time >180 minutes
Cardiac dysfunction on Echo	Ventilator support	Donor recipient weight mismatching
High-dose inotropic support	Intravenous inotropic support, mechanical support	Female donor to male recipient
Cause of brain death	Pulmonary hypertension	Concomitant lung retrieval
Primary graft dysfunction of other organs	Overweight, diabetes mellitus	

factors for bacterial sepsis that are of particular importance for the heart transplant recipient include pre-transplant mechanical or ventilator support and the need for high-dose perioperative immunosuppression. Other factors associated with an increased risk of sepsis in the ICU patient such as previous colonisation with multiresistant bacteria, large-volume blood loss and transfusion, acute renal failure and prolonged ventilation or placement of intravenous lines also apply to the heart transplant recipient. Classic signs of sepsis such as high fever may be masked or blunted by immunosuppressive therapy so a high index of suspicion is required. Infections usually respond to conventional antibiotic therapy but choice will depend on local sensitivities. Herpes simplex is common in the early post-transplant period but usually responds to oral aciclovir (acyclovir). Clinical infections with other viruses (e.g. herpes zoster and cytomegalovirus) usually have a more delayed onset after the ICU phase of treatment. Oropharyngeal candidiasis is probably the most common fungal infection and is usually preventable with oral nystatin. Occasionally, patients may present with early candidaemia, which is an important differential in the acutely septic patient. Other fungal infections such as *Aspergillus* may also occur during the immediate postoperative period but more typically occur at a later time point.

ACUTE REJECTION

Acute rejection is an adaptive immune response mounted by the recipient against the transplanted donor organ. Classical acute rejection is predominantly

a T-lymphocyte-mediated inflammatory response directed against the grafted organ. As the rejection response progresses, graft injury in the form of myocyte necrosis and myocardial oedema develop. In more severe rejection, other inflammatory cells such as eosinophils and neutrophils are recruited into the myocardium and myocardial haemorrhage may occur. Acute cellular rejection can occur at any time post-transplantation but is unusual during the first week postoperatively. Acute rejection may be suspected on clinical grounds but is often completely asymptomatic. Symptoms are often non-specific and include fatigue, dyspnoea and fever.

Diagnosis is based on the pathological finding of a lymphocytic inflammatory infiltrate on endomyocardial biopsy and the grading of severity is based on the extent of the inflammatory infiltrate and the presence or absence of myocyte necrosis.[44] Most transplant programmes perform regular surveillance endomyocardial biopsies commencing at about 1 week post-transplant. Biopsies are repeated weekly for the first month post-transplant, fortnightly between months 1 and 3, monthly between months 4 and 6 then less commonly thereafter. Endomyocardial biopsy may be performed at any time between scheduled biopsies if there is clinical suspicion of rejection. The preferred vascular access for endomyocardial biopsy is the right internal jugular vein and this should be considered when placing central venous lines for critical care purposes.

The overall rate of biopsy proven acute rejection has been declining in recent years probably as a result of more effective maintenance immunosuppressive therapy.[1] Historically, most patients experienced one or more episodes of acute rejection requiring 'pulsed' steroid therapy (e.g. i.v. methylprednisolone 0.5–1.0 g daily for three doses) during the first 3 months after transplantation; however, recent registry reports indicate that only one in three heart transplant recipients will experience an acute rejection episode requiring pulsed immunosuppressive treatment during the first 12 months.[1]

Antibody-mediated rejection is also now recognised as a major cause of graft injury and loss.[45] It occurs as a result of the formation of donor-specific antibodies (DSA) in the recipient that are directed usually against donor HLA antigens. These may be present pre-transplant as a result of previous transfusions, organ transplants, viral infections or pregnancies. Hyperacute rejection (HAR) occurring during the first hours or days post-transplant is usually triggered by the presence of preformed DSA in high circulating titres. Fortunately, this is now a rare event as DSAs are normally detected by prospective or virtual cross-matching between the donor and recipient.[46] HAR often presents with rapid onset of severe graft dysfunction and may be difficult to distinguish from primary graft failure. Apart from acute circulatory support, treatment involves high-dose intravenous steroids, plasmapheresis and intravenous immunoglobulin (IVIG). In more severe cases, monoclonal antibody treatments have been used including rituximab, bortezomib and eculizumab.

LUNG TRANSPLANTATION

SELECTION OF PATIENTS FOR LUNG TRANSPLANTATION

As with heart transplantation, the primary indication for lung transplantation is the presence of advanced lung disease for which there is no alternative therapy. Guidelines for eligibility and selection criteria for lung transplantation have been extensively reviewed elsewhere.[47,48] The major disease categories are COPD/emphysema including α_1-antitrypsin deficiency, pulmonary fibrosis, cystic fibrosis, bronchiectasis and pulmonary vascular disease.[2] Collectively these diseases account for more than 90% of cases. Transplant procedures for pulmonary fibrosis have increased steadily during the last decade from 16% of all procedures in 2000 to 28% in 2009.[2] Bilateral lung transplantation has become the most commonly performed lung transplant procedure for all major lung diseases and in the most recent report of the ISHLT Registry accounted for 72% of all transplants.[2] Single lung is still occasionally performed for non-AAT-deficiency-associated COPD/emphysema and pulmonary fibrosis but rarely for other lung diseases. Combined heart–lung transplantation is now a relatively rare procedure and is largely restricted to patients with pulmonary vascular disease in association with complex congenital heart disease or coincidental severe end-stage heart and lung disease.

A critical aspect of the decision making regarding suitability for lung transplantation is the capacity of the patient to survive the stresses of lung transplant surgery. For this reason, patients who are too unwell either acutely or chronically have been considered unsuitable for lung transplantation. Objective criteria for defining these characteristics have been lacking, however, and decisions regarding capacity to survive the stress of surgery have to a large extent been based on clinical judgement.[46] Among the former are those with terminal respiratory failure requiring prolonged ventilator support with or without other organ failure. Among the latter are those who are malnourished, weak and cachectic due to chronic illness. Quantitative measures of frailty may provide a more objective measure on which to base decisions regarding suitability for transplantation; however, considerable further research is required.[49] The problem has been further compounded by the lack of a safe and effective 'artificial lung' to enable patients with advanced respiratory failure to be weaned from acute ventilator support and to participate in some form of rehabilitation programme prior to transplant surgery. ECMO support in awake patients or the use of pumpless carbon dioxide removal

devices (e.g. Novalung) may go some way towards addressing this limitation.[50,51]

LUNG TRANSPLANT SURGERY

Bilateral lung transplantation was initially developed as an en bloc technique with a single tracheal anastomosis; however, the high incidence of tracheal anastomotic complications has led to this procedure largely being replaced by the technically simpler bilateral sequential single-lung transplant (BSSLT) procedure. BSSLT is most commonly performed with the larger right lung transplanted first followed by the left lung. The surgical approach may be via a midline sternotomy, horizontal bilateral thoracosternotomy (clam shell incision), or two smaller anterolateral thoracotomies (where the sternum is not divided). The operation may be performed with or without cardiopulmonary bypass, depending on the ability of the native lung to sustain the cardiac output and ventilation during implantation of the first lung and then the ability of the transplanted lung to sustain the cardiac output and ventilation during implantation of the second lung. Although cardiopulmonary bypass ensures the maintenance of adequate ventilation and vital organ perfusion, it requires anticoagulation and its use is associated with an increased risk of perioperative bleeding. Cardiopulmonary bypass does, however, offer the advantage of better operating conditions and importantly it allows control of donor lung reperfusion conditions. In the absence of cardiopulmonary bypass, the newly transplanted right lung must take over ventilation in order for the left lung to be implanted. At this time the transplanted right lung will receive the entire cardiac output and this can be detrimental. Cardiopulmonary bypass appears to have no deleterious effect on early lung function or clinical outcome.[52] A cuff of donor left atrial tissue containing the confluence of the two pulmonary veins is anastomosed to the recipient left atrium followed by the anastomosis of the donor to recipient pulmonary artery and finally the donor to recipient main bronchus.

Single-lung transplantation is performed via a thoracotomy on the corresponding side with the order of anastomoses being bronchus, left atrium and pulmonary artery. Combined heart–lung transplantation is the most extensive cardiothoracic transplant and is now restricted almost exclusively to patients with complex congenital heart disease complicated by irreversible pulmonary vascular disease. The operation is performed on cardiopulmonary bypass as an en bloc procedure with sequential anastomosis of the trachea, right atrium and aorta. Uncontrollable bleeding from adhesions formed during previous thoracic operations or from systemic to pulmonary arterial collaterals is a major cause of operative death in these patients. Surgical damage to major nerves (e.g. vagus, phrenic and recurrent laryngeal) is a potential complication of heart–lung transplantation and may contribute to postoperative morbidity.

POST-TRANSPLANT MANAGEMENT

IMMEDIATE POST-TRANSPLANT CARE AND MONITORING

Lung transplant recipients, like heart transplant recipients, are transferred from the operating room to the ICU bed still anaesthetised, intubated and ventilated. Bronchoscopy is performed in the operating room and later in the ICU. This is to check the bronchial anastomosis and to suction any secretions. In the uncomplicated case after transfer to the ICU, sedation will be weaned and the patient extubated when sufficiently conscious, usually within 24 hours of surgery. Routine monitoring includes an ECG, arterial line, Swan–Ganz catheter and urinary catheter. Upper and basal pleural drains will be in place and are placed on continuous suction. Air leaks can occur in the first few days post-transplant but are usually of small volume and self-limiting.

PHYSIOLOGY OF THE TRANSPLANTED LUNG

Transplantation of the lungs results in denervation below the level of the bronchial anastomosis (or below the tracheal anastomosis in the case of heart–lung transplantation). The main functional consequence is loss of the normal cough reflex and markedly impaired mucociliary clearance distal to the anastomosis, so patients are at high risk of sputum retention during the early postoperative phase. Respiration both at rest and in response to exercise is unaffected by lung denervation. Pulmonary vascular resistance, airway resistance and reactivity also appear to be unaffected by lung denervation.

VENTILATORY AND INOTROPIC SUPPORT

Postoperative ventilatory support varies according to the type of transplant. A normal endotracheal tube can be placed for double-lung and heart–lung transplant recipients. Occasionally, single lung transplant recipients may require placement of a double-lumen endotracheal tube to allow differential ventilation of the native and transplanted lungs. Chronotropic and inotropic support are routine for heart–lung transplantation but are not routinely required after single and BSSL transplantation.

Ventilator settings are similar to those used for patients undergoing major lung surgery with the aim being to minimise the risk of ventilator-induced lung injury. The Fi_{O_2} is rapidly reduced to the lowest level sufficient to maintain a Pa_{O_2} in the range 80–120 mmHg (10.64–15.96 kPa). Where possible, the tidal volume is kept below 6–8 mL per kg and the ventilator frequency is adjusted to maintain a peak inspiratory pressures below 30 cm H_2O. Positive end-expiratory pressure

(PEEP) will be set at 5–10 cm H_2O but may be increased depending on requirements. If arterial blood gasses are adequate the patient is woken and progressed towards extubation. This will involve a gradual withdrawal of ventilatory support.

IMMUNOSUPPRESSION

Induction therapy is used in approximately half of all lung transplant programmes. There has been an increase in the use of induction therapy in the most recent era, with a move away from polyclonal antithymocyte preparations to IL-2R antagonists or alemtuzumab.[2] ISHLT Registry data suggest a small improvement in survival in patients receiving induction therapy; however, this is based on a retrospective, non-randomised comparison.

As with heart transplantation, maintenance immunosuppression in lung transplant recipients initially involves the administration of three drugs in combination: high-dose corticosteroids, an antimetabolite (mycophenolate mofetil (MMF) or azathioprine) and a calcineurin inhibitor (CNI, ciclosporin or tacrolimus). Tacrolimus and MMF are the preferred CNI and antimetabolite in the majority of lung transplant programmes.[2] Recipients with cystic fibrosis are administered their calcineurin inhibitor with a pancreatic enzyme supplement on a t.d.s. schedule.

INFECTION PROPHYLAXIS

Lung transplant recipients are at high risk of infection, more so than other organ transplant recipients. In addition to being transplanted into a heavily immunosuppressed recipient, the transplanted lung uniquely is in direct contact with the external environment and any potential airborne pathogens. Often the donor has evidence of lower airway colonisation or even infection prior to lung retrieval. There is impaired ciliary function and loss of the cough reflex below the bronchial/tracheal anastomosis resulting in retained secretions below the anastomosis. In addition, a substantial proportion of lung transplant recipients – those with cystic fibrosis or bronchiectasis – are invariably colonised with multiresistant bacteria in the upper respiratory tract at the time of transplantation. These organisms can rapidly spread to the lower respiratory tract.

Bacterial prophylaxis

Donor sputum or bronchoscopy samples are taken prior to or at the time of lung retrieval and are used to guide antibiotic therapy in the recipient. For recipients with chronic suppurative lung disease prior to transplant, antibiotic prophylaxis will depend on sensitivities determined from pre-transplant surveillance. For other lung transplant recipients a third-generation cephalosporin with broad spectrum against Gram-positive and -negative organisms (e.g. cefotaxime) is administered.

Fungal prophylaxis

As with heart transplantation, *Pneumocystis jiroveci* prophylaxis usually in the form of oral co-trimoxazole is commenced in the first week post-transplantation and continued indefinitely. For patients who are allergic to sulfonamides, oral dapsone or monthly inhaled pentamidine is a suitable alternative. Nystatin oral solution to prevent oropharyngeal candidiasis is also administered for the first few weeks post-transplant. *Aspergillus* infections are less common but potentially catastrophic. Inhaled amphotericin (preceded by inhaled bronchodilators) has been shown to significantly reduce the incidence of *Aspergillus* and other fungal infections and is administered routinely as a b.d. or t.d.s. dose until hospital discharge.[53]

Viral prophylaxis

CMV may cause life-threatening pneumonitis in the lung transplant recipient and has been associated with increased risk of later development of bronchiolitis obliterans syndrome. Risk is highest in recipients of lungs from CMV-seropositive donors, particularly when the recipient is CMV negative (D+/R–). Although clinical infection is extremely uncommon in the first month post-transplant, it is essential to commence prophylaxis immediately post-transplant. Intravenous ganciclovir is administered initially followed by oral valganciclovir (dose adjusted for renal function) once the recipient is able start oral medications. Valganciclovir is continued indefinitely in D+/R– patients and for 6 months in D+/R+ and D–/R+ recipients. CMV hyperimmune globulin is also administered for up to 1 month to D+/R– recipients in some institutions. Recipients who are Epstein–Barr Virus (EBV) naïve who receive lungs from EBV-seropositive donors (D+/R–) are at high risk of developing post-transplant lymphoproliferative disease (PTLD), which carries a very high mortality. If not already receiving oral valganciclovir, EBV D+/R– recipients are maintained on valaciclovir indefinitely.

Other routine drugs administered in the immediate post-transplant period include an insulin infusion as required to control hyperglycaemia, which is common following administration of high-dose steroids, proton pump inhibitors to prevent peptic ulceration, domperidone and sucrulfate to prevent gastro-oesophageal reflux and calcium and vitamin D supplements to prevent osteoporosis. A typical post-transplant drug treatment protocol is shown in Table 102.3.

COMPLICATIONS

PRIMARY GRAFT DYSFUNCTION AND FAILURE

Primary graft dysfunction (PGD) is defined as an acute non-immune-mediated injury to the transplanted lung occurring within the first 72 hours postoperatively. PGD has been reported in up to 25% of lung transplant

Table 102.6 ISHLT Grading system for primary graft dysfunction after lung transplantation

PGD GRADE	Pa_{O_2}/Fi_{O_2}	RADIOGRAPHIC INFILTRATES CONSISTENT WITH PULMONARY OEDEMA
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

Table 102.7 Recognised risk factors for primary graft dysfunction after lung transplantation

DONOR FACTORS	RECIPIENT FACTORS	PROCEDURAL FACTORS
Age >50 years	Age >60 years	Prolonged ischaemic time
Smoking >10 pack years	Ventilator or ECMO support	
Pneumonia on CXR or purulent secretions on bronchoscopy	Pulmonary fibrosis	
Primary graft dysfunction of other organs	Pulmonary hypertension	
	Obesity	

recipients. The syndrome is manifested as impaired oxygenation and the presence of pulmonary alveolar opacities on CXR. The extent of the abnormalities in these two parameters has been used to grade the severity of the syndrome from absent (Grade 0) to severe (Grade 3) (**Table 102.6**).[51] In its most severe form, PGD3 results in a fulminant adult respiratory distress syndrome (ARDS). In this instance, there is rapid deterioration in gas exchange associated with increased pulmonary vascular resistance, reduced lung compliance and diffuse bilateral alveolar infiltrates on CXR. The major underlying cause is thought to be ischaemia reperfusion injury to the transplanted lungs, but other factors such as acid aspiration, pneumonia and ventilator-induced barotrauma may contribute (**Table 102.7**). Risk factors include prolonged graft ischaemia, increasing donor age and recipient diagnosis of pulmonary hypertension.[7]

Severe PGD is the major cause of early mortality after lung transplantation with a reported mortality of up to 50%. It is also associated with increased acute morbidity related to the need for prolonged ventilation and ICU stay, prolonged hospital stay and delayed recovery of lung function. For recipients who survive an episode of severe primary graft dysfunction, there are data suggesting that long-term outcomes are adversely affected.

Treatment is supportive and aimed at maintaining adequate gas exchange until the syndrome resolves. Inhaled nitric oxide has been shown to improve gas exchange and lower pulmonary vascular resistance acutely in PGD but has not been found to affect overall survival. In the most severe cases, ECMO support may be required to maintain oxygenation and remove carbon dioxide.

INFECTIONS

The infectious agents of most concern during the immediate post-transplant period are multiresistant bacterial pathogens, particularly in those undergoing transplantation for chronic suppurative lung disease. Pneumonia is the most common infectious complication and the risk is further increased by the need for prolonged ventilation (in the case of primary graft dysfunction) and airway complications (discussed below). Choice of antibiotic is based on in vitro sensitivities. As mentioned, fungal infections are less common but may be catastrophic. Angioinvasive *Aspergillus* infection may result in rapidly progressive necrotising pneumonia, bronchial anastomotic dehiscence or even pulmonary arterial or venous anastomotic dehiscence leading to exsanguinating haemoptysis. An aggressive diagnostic approach including bronchoscopy with bronchial washings or CT-guided fine needle aspiration of focal pneumonic lesions is essential to facilitate early diagnosis and initiation of appropriate antibiotic or antifungal treatment.

ACUTE REJECTION

The incidence of acute rejection after lung transplantation has been declining as it has for heart transplantation. Based on the most recent report from the ISHLT Registry, approximately one-third of lung transplant recipients develop acute rejection during the first 12 months after transplantation. Symptoms and signs of rejection are non-specific and include dyspnoea, cough, sputum production, fever, declining FEV_1 on spirometry and the appearance of alveolar infiltrates on CXR. The major differential diagnosis is lower respiratory tract infection. If unrecognised and untreated, acute rejection can lead to rapid onset of severe graft dysfunction and a clinical picture of ARDS. It is important to remember that rejection and infection can occur simultaneously. Transbronchial lung biopsy performed at the time of bronchoscopy and bronchial washing is required to confirm the diagnosis pathologically. As with heart transplantation, the severity of acute lung rejection is graded histologically.[54] Treatment for biopsy proven acute rejection in the first instance involves pulsed intravenous or oral steroid therapy.

Graft dysfunction occurring during the first 72 hours after transplantation is usually due to primary graft dysfunction; however, graft dysfunction occurring at any time after this suggests another cause – usually either infection or rejection. Acute cellular rejection is very uncommon in the first week post-transplant but acute antibody-mediated rejection (AMR) may occur if there are preformed donor-specific antibodies. AMR may result in severe graft dysfunction and be difficult to distinguish from PGD. Treatment of acute AMR is intensive and involves a combination of plasmapheresis, administration of high dose intravenous immunoglobulin (IVIG) and rituximab.

AIRWAY COMPLICATIONS

In most lung transplant operations, the surgeon does not attempt to restore the bronchial blood flow to the transplanted lung. Establishment of bronchial blood flow to the transplanted lung does occur over the first month post-transplant via ingrowth of collaterals from the recipient, but until then the transplanted lung is reliant on low-pressure retrograde collateral bronchial flow of (deoxygenated) blood from the pulmonary artery.[55] For these reasons the donor bronchus is relatively ischaemic during the first few weeks after transplantation and this predisposes to a number of airway complications including bronchial stenosis at or beyond the anastomosis, bronchomalacia, endobronchial infections and bronchial anastomotic dehiscence. The latter is often associated with persistent large air leaks from pleural or mediastinal drains and development of fatal mediastinitis. Repeated bronchoscopic assessment of the anastomosis is undertaken during the first 4–6 weeks until healing is complete. A variety of bronchoscopic interventional procedures have been developed to treat the different airway complications.[55]

CONCLUSIONS

Heart and lung transplantation have emerged as the most effective treatments available for patients with end-stage heart or lung disease. Transplantation of both organ transplants is limited by donor numbers so that only a small percentage of patients who might benefit are able to undergo the procedure. The severe shortage of donor organs has resulted in an increased utilisation of marginal donors with an associated risk of primary graft dysfunction or failure, which poses significant challenges during the initial ICU management of these patients. Nevertheless, the large majority of heart and lung transplant recipients make an excellent recovery following transplant surgery and return to a quality of life that is close to that of normal people of the same age. Almost two-thirds of heart transplant recipients live for more than 10 years and one-third live for more than 20 years after transplantation. Long-term survival of lung transplant recipients is less than that of heart transplant recipients but has been improving steadily. Improvements in donor management and organ preservation should increase the number of cardiothoracic organs available for transplantation, while ongoing refinements to post-transplant management are likely to result in further improvements in the long-term survival of these patients.

The critically ill child

Shelley D Riphagen

The chapters on paediatric intensive care are intended to help intensivists outside specialist paediatric centres manage common paediatric emergencies. They should be read in conjunction with relevant adult chapters, as there are many areas of commonality.

Compared with adults, there are a number of differences in neonates, infants and young children that render them more susceptible to disease and the progression to critical illness.

Very importantly, young children are unable to verbalise their complaints and the concerned responsible care-giver/parent must be listened to and taken seriously. Parents are usually very knowledgeable about their child's normal behaviour, and a non-specific change in behaviour, especially a change in the level of activity, alertness or feeding, may be the young child's only sign of developing critical illness. This difference from adults makes children more at risk of being 'ignored' or parents of being falsely reassured until the child is quite evidently critically ill with organ dysfunction.

There are, however, many similarities with adults in terms of organ support and monitoring, and the provision of intensive care for children is in many respects a scaled-down version of available adult technology.

Some of the important differences between adults and children are described below.

CARDIORESPIRATORY ADAPTATION AT BIRTH

Dramatic physiological adaptation takes place at birth. Intracardiac pressure relationships in the fetal circulation undergo significant changes associated with clamping of the umbilical cord and disconnection of the placenta, with its supply of vasodilating hormones. At the same time, the newborn takes the first breath of air, resulting in a sudden fall in pulmonary vascular resistance, increase in pulmonary blood flow and left atrial return with increase in left-sided pressures and subsequent physiological closure of both the foramen ovale and the ductus arteriosus. All blood, which previously short-circuited the right side of the fetal heart and lungs via the foramen ovale is forced to follow the postnatal/adult pattern of circulation.

Although there is a dramatic fall in pulmonary vascular resistance at birth, changes initiated at the time of birth are incomplete and progressive, with further reduction in pulmonary vascular resistance associated with regression in arteriolar muscularisation.

Reversion to fetal physiology, however, may occur during the first days to weeks of life in the case of respiratory pathology, or other causes of hypoxia and acidosis. Reversion to fetal pattern circulation means that desaturated blood short-circuits the lungs through the foramen ovale, resulting in further profound desaturation and hypoxaemia, with consequent increases in pulmonary vascular resistance and the development of a vicious cycle. Urgent reversal of the hypoxaemia must be instituted to prevent progression to death.

Pulmonary circulation pathophysiology is probably related to abnormalities of endogenous nitric oxide production and manipulation of this agent has proven useful in therapy.[1]

CAUSES OF TRANSITIONAL (POST-NATAL REVERSION TO FETAL) CIRCULATION

A 'fetal' pattern may persist due to:

- low lung volume states (e.g. hyaline membrane disease and perinatal asphyxia)
- pulmonary hypoplasia (e.g. diaphragmatic hernia and Potter's syndrome)
- meconium aspiration syndrome
- chronic placental insufficiency
- perinatal hypoxia and acidosis from any cause
- sepsis (e.g. group B streptococcal infection)
- hyperviscosity syndrome.

Return to fetal circulation may need to be medically or surgically induced in the case of 'duct dependent' congenital cardiac defects associated with either obstructive lesions on the right or left side of the heart, and as a temporising measure in the case of transposition of the great arteries. This may be achieved by infusion of prostaglandin E_2 (a placental-derived dilating hormone) and/or re-opening of the foramen ovale by balloon atrial septostomy via the femoral or umbilical vein/or open septectomy.

Some intracardiac or vascular shunt lesions result in high pulmonary blood flow and increasing pulmonary pressure states. Left untreated this elevated pulmonary vascular resistance may become fixed, and make subsequent surgical repair unfeasible.

GROWTH AND DEVELOPMENT

There is progressive growth and maturational development of all organ systems throughout childhood. This necessitates knowledge of normal/expected parameters and organ function at different ages in childhood. Drug and equipment calculations are age or weight based, and there is less room for error. Small miscalculations, depending on the size of the child, may have significant implications. Physiologically, organs in children are still undergoing maturation, and have not reached full potential to deal with superadded stresses and drug metabolism in some instances. Incomplete maturation of renal and liver function, specifically in neonates needs to be considered. Similarly, the ability to recover from injury in children is better than in adults because of the ongoing growth and development occurring in early childhood. Premature infants with significant 'chronic lung disease' may still have potential to recover near-normal lung function in adulthood. The brain in children undergoes significant continued maturation and development in early childhood and neural plasticity may allow for seemingly remarkable recovery from certain types of brain injury.

MATURATION

The immaturity of systems and biochemical processes at birth alters the physiological response to stress and drugs. Thermoregulation, immune function, respiratory, renal, hepatic and neurological function are all immature at birth, even in the full-term infant. This immaturity is magnified in the preterm infant with associated surfactant deficiency causing respiratory distress, liver glucuronyl transferase deficiency causing jaundice, and the necessity to be nursed in a thermo-controlled environment. Human body temperature is maintained within narrow limits. This is achieved most easily in the thermoneutral zone – the range of ambient temperature within which the metabolic rate is at a minimum. Once ambient temperature is outside the thermoneutral zone, heat production (shivering or non-shivering thermogenesis) or evaporative heat loss processes are required to maintain body temperature within normal limits. Regulatory mechanisms are less effective in the neonate (there is no shivering or sweating), who is otherwise disadvantaged by a high surface area to body weight ratio and lack of subcutaneous insulation.

The thermoneutral zone is higher in premature infants and falls with increasing postnatal age. Oxygen consumption is minimal, with an environmental or abdominal skin temperature of 36.5°C. Oxidation of brown fat found in the interscapular and perirenal areas (non-shivering thermogenesis) is the major source of heat production when 'cold stressed'.

Alteration of body temperature above or below normal leads to increased or decreased metabolism respectively. Attempts by the body to maintain body temperature within normal limits are associated with increased metabolism and cardiorespiratory demands. Radiation is a major source of heat loss in the neonate and is effectively minimised by double-walled incubators or by servo-controlled radiant heaters. The latter allow better access to critically ill babies for monitoring and procedures. Cold stress per se, increases neonatal mortality. In the presence of respiratory or cardiac disease, it may lead to decompensation.

SPECTRUM OF DISEASE

Congenital structural abnormalities of major systems including the heart, lung, brain and skeleton, among others, are usually evident at birth, however some may become exposed in early childhood.

Inborn errors of metabolism, although present from birth, may become evident only during an intercurrent period of stress, something as seemingly insignificant as weaning onto solids or a mild respiratory tract infection.

The immature immune system puts children at higher risk than adults for the development of serious bacterial and viral illnesses. The inflammatory response of the newborn is attenuated. Febrile response to infection may be lacking and both cellular (chemotaxis and phagocytosis) and humoral (complement activity and opsonisation) responses may be impaired. Cell-mediated immunity is significantly compromised in infants born without thymic function (DiGeorge syndrome) but in the normal newborn, T-cell function appears to be quite well developed. Rejection of skin allografts is slower in the newborn but this seems to be related mainly to the attenuated inflammatory response. The B-cell system, responsible for antibody production, is immature at birth, however the neonate has passive immunity against some infections because of transplacental transfer of maternal antibodies. Additional natural immunity is acquired as a result of immunoglobulin A (IgA) in breast milk, which protects against some acquired gastrointestinal infections. Overall, the immaturity and inexperience of the immune system result in a markedly increased susceptibility to infection in the first 6 months of life. Congenital abnormalities of the immune system usually present in childhood with recurrent or overwhelming infection.

The response to any illness may be physiologically immature and the mode of presentation much less well defined than in adults. For the most part, however, children are the scaled-down version of adults and, after the neonatal period, physiological principles that apply in adults generally apply also in children.

MANAGEMENT OF THE CRITICALLY ILL CHILD

Of paramount importance in the management of critically ill children are early recognition, appropriate

resuscitation and adequate stabilisation prior to transfer to a tertiary institution with paediatric intensive care facilities.[2]

RECOGNITION

Recognition of critically ill children is slightly more difficult than in adults for a number of reasons. Children of various ages have different normal physiological parameters and it is important for those dealing with children to be familiar with these norms. For those unfamiliar or infrequently involved in the care of critically ill children, it is important to have a readily available information source of normal values for the specific aged child they are dealing with at the time. Resources are available on the internet and as hand-held applications to provide ready access to this information.

Non-verbal and younger children lack the communication skills to express their malaise in a specific manner. Generically as children become more unwell they will become lethargic, go off their meals and eventually may start vomiting. Older children respond in the same ways as adults with appropriate pyrexia to an infective trigger, whereas very young children, and especially neonates, may become hypothermic. Tachycardia is one of the most important signs in the deteriorating child, and an unexplained tachycardia or one that does not respond to antipyresis and analgesia must be regarded very seriously. As a child's condition deteriorates, the child may progress from being cool peripherally with a palpable peripheral to central temperature difference, to peripheral mottling and eventually a prolonged central capillary refill time. Pulses in the deteriorating child may be noticeably different peripherally from those taken centrally, even in those with a preserved blood pressure. Disinterest in eating and then drinking, which may progress to vomiting, suggests the development of ileus and gastric stasis as perfusion to the gut is reduced. Visceral perfusion abnormality may also be noticed by the parents, as they report abdominal distension or reduction in wet nappies or passing urine. During all this time, the deteriorating child may still have perfectly normal saturations and remain lucid, though with increasing drowsiness. Increasing tachypnoea may not necessarily identify a respiratory focus of decompensation, but may represent the attempt to compensate for the metabolic acidosis associated with shock.[3,4]

In summary, the skill involved in recognising the deteriorating child early, relies on careful history-taking with acknowledgement that the parents know what is normal for their child. Alteration from normal must not be ignored or dismissed until the child has been thoroughly and thoughtfully examined. Physiological and biochemical parameters that are not normal must be critically evaluated to ensure that the early signs of decompensation are not missed. Attempt must be made to treat what is presumed wrong, with the intention that the response to treatment results in normalisation of the physiological disturbance. If this is not the case, the child should remain under vigilant review, with a senior or specialist opinion sought to ensure that a diagnosis has not been missed.

RESUSCITATION

Identification and treatment of the most likely diagnosis, awareness of the potential differential diagnosis and repeated evaluation of response to treatment are all key to the successful management of a critically ill or injured child. Successful treatment should return physiological parameters to normal. If this does not occur, escalation of resuscitation may require more invasive organ support in the form of ventilation, infusion of inotropes, provision of renal, hepatic and haematological support. In extreme cases, extracorporeal life support may be required.[2]

STABILISATION AND TRANSFER

Stabilisation of a critically ill child at a referral hospital prior to transfer infers resuscitation has begun, physiological parameters are stable or returning towards normal and the appropriate level of all organ support required is in place. In some situations, the organ support required (for example haemofiltration) may not be available during the retrieval process, and it is important to minimise delay of the transfer to a place where equipment and staffing levels are present to optimise the eventual outcome of the child.[5]

Good stabilisation implies that the child has had all resuscitation procedures completed at the referral hospital and the child has appropriate airway and vascular access contingency plans to deal with destabilisation during the transfer. Ventilated children, for example, should have the appropriate-sized endotracheal tube confirmed in ideal position, a gastric tube to decompress the stomach and facilitate ventilation and the adequacy of ventilation monitored with continuous oxygen saturations and end-tidal carbon dioxide monitoring.

Children who have required volume resuscitation, are on inotropes or who are potentially cardiovascularly unstable should have enough vascular access to allow commencement or escalation of inotropes during transfer. Adequate cardiovascular monitoring, in the form of continuous cardiac trace and regular intermittent non-invasive or continuous invasive blood pressure monitoring, should be in place.

Arterial access in children is indicated in those who are cardiovascularly unstable and/or on inotropes, those who need targeted blood pressure (e.g. for intracranial perfusion pressure) and those who require frequent blood gas monitoring. Peripheral arteries including radial, dorsalis pedis and posterior tibial are preferable. Central arterial access attempts should completely avoid the brachial artery, as it is an end artery,

and thrombosis may lead to limb loss. Attempt should be made to minimise blood gas monitoring by correlation of end-tidal CO_2 with Pa_{CO_2}. Excessive blood gas monitoring and the performance of blood tests that do not result in changes of treatment eventually result in the need for red cell transfusion. The risk–benefit of this practice must be considered.

Vascular access may be extremely challenging in critically ill children and familiarity with intraosseous needle insertion[6,7] and the use of the external jugular vein, may provide rapid access for the early commencement of resuscitation fluids. Intraosseous access is technically easy and provides 'central' access to a non-collapsible venous system, into which almost all resuscitation drugs can be rapidly infused. The limb accessed must be carefully monitored.[8] Placement of central venous lines (femoral and jugular) in children is technically more difficult than in adults, because of the diminutive size of the vessels, short neck in small children and bleeding problems that may be present in critical illness. Central venous cannulation should be attempted only by those skilled in this procedure.[9] Femoral central venous access is preferable to jugular access in children who have a coagulopathy or any suggestion of raised intracranial pressure. Catheters utilising the Seldinger technique have greatly increased successful placement. Ultrasonography is useful to determine the exact location of veins. Multilumen catheters are recommended when infusing multiple drugs and for parenteral nutrition. Complications including catheter-related sepsis are the same as in adults. This risk can be reduced by adherence to a bundle of measures.[10] The need for prolonged venous access may warrant regular catheter changes, or surgical implantation of a central venous device (e.g. Infusaport, Broviac or Hickman catheter).

In children undergoing resuscitation, a urinary catheter with hourly fluid balance allows a more complete assessment of adequacy of resuscitation. It is not expected that the child will immediately recover during the resuscitation and stabilisation process and so the delay in transferring the child to a definitive place of care should be minimised and be specific to the requirements of each patient.

PAEDIATRIC INTENSIVE CARE TRANSFER

Transfer by a team skilled in the retrieval of critically ill children is associated with reduced morbidity, critical incidents and mortality.[11] There are, however, some circumstances where the disease process is time critical, and the time delay in awaiting a paediatric retrieval team imposes an unacceptable risk.[12] In these cases it is important to use the most competent and skilled team available at the time, usually an anaesthetist, paediatrician and adult intensive care nurse. Advice and remote telephonic assistance should be available from the paediatric retrieval team or accepting PICU. For those performing time critical retrievals, it is essential that delay is minimised and only life-saving procedures are allowed to delay the transfer. In these cases it is helpful to have a discussion with the accepting team, in terms of their expectations for transfer and also of what to expect about the patient's condition. A checklist for retrieval is helpful to ensure that all eventualities have been considered.

PAEDIATRIC INTENSIVE CARE

The development of paediatric intensive care units (PICU) separate from adults, recognised the unique diseases, problems and requirements of critically ill children. Centralisation and modernisation of paediatric intensive care, along with dedicated paediatric retrieval teams, have dramatically improved outcomes in children. Critical illness or injury in children is not common, and the reduced incidence of disease means that centres that see more of a specific illness become more skilled at dealing with it, and children have better outcomes. Super-specialisation of paediatric intensive care is evolving, for example in the care of children with highly complex congenital cardiac lesions.[13]

The paediatric intensive care unit does not function in isolation and the intensive care team needs support from all other paediatric sub-specialties in providing the highest level of comprehensive care for this group of children. The PICU is only one part of the delivery of tertiary paediatric hospital care to children, which starts with the provision of excellent pre-hospital care; advice and support for level I and 2 hospitals in the resuscitation and stabilisation of critically ill children; and the subsequent safe transfer by specialised paediatric intensive care retrieval teams to the appropriate paediatric intensive care unit.

The adult intensive care unit, with its technically skilled nursing and medical team, may be an appropriate and safe place for a critically ill child to await retrieval, as long as the adult ICU team is appropriately supported by local paediatric consultants, and the paediatric retrieval team or accepting PICU continue to provide management advice on the critically ill child.

MINIMUM STANDARDS

Suggested minimum standards for a PICU should be adopted. In general a PICU should provide:

- a specialist trained in paediatric intensive care available at short notice, and available 24/7 for ongoing management advice
- a comprehensive range of paediatric sub-specialty support
- immediately available junior medical staff with advanced life support skills including advanced airway and vascular access competence
- nursing staff with experience in paediatric intensive care, and a nurse : patient ratio to facilitate the appropriate level of care

- allied health professionals with specific training in paediatrics including ready access to physiotherapists, dieticians, pharmacists, speech and language therapists, occupational therapists and child psychologists as well as ancillary support staff including clerical and portering staff
- specialised advanced life support equipment for children ranging in age from neonates to adolescents
- 24-hour laboratory, radiological and pharmacy services
- purpose-built PICU, recognising the special physical and emotional needs of critically ill children and their families
- a programme for teaching, continuing education, research and quality assurance
- the skills and expertise to transfer critically ill children within the hospital for investigations and treatment
- an in-house paediatric intensive care retrieval team, or at least an arrangement with an external retrieval team to provide critical care transfer of children into the PICU.

Neonatal intensive care units have many similar, but also additional other requirements.

PAEDIATRIC MONITORING

Technology has allowed most aspects of adult monitoring to be applied to neonatal and paediatric practice. The ideal paediatric haemodynamic and respiratory monitoring system should:[14,15]

- be non-invasive, painless and readily interfaced with the child
- constitute minimal risk to the child
- provide specific data relevant to the child's status that are reproducible and readily understood
- respond rapidly to changes in status
- provide continuous visual and/or auditory display of data
- have appropriate alarms
- have facilities for recording data
- be inexpensive and require low maintenance.

PULSE OXIMETRY

Pulse oximetry provides continuous non-invasive measurement of arteriolar saturation (Sa_{O_2}) and provides a rapid indication of hypoxaemia. Accurate information is given:

- when the oxyhaemoglobin dissociation curve is shifted to the left (e.g. fetal haemoglobin and alkalosis) or to the right (e.g. sickle-cell disease and acidosis)
- in the presence of carboxyhaemoglobin (functional saturation is accurate)
- with moderately severe desaturation (e.g. cyanotic heart disease)
- with anaemia (haemoglobin concentrations above 5 g/dL)
- when skin is pigmented.

Errors occur with extreme hypoperfusion, excessive movement and rapidly changing ambient light. A range of sensors are now available to monitor children of all ages.

TRANSCUTANEOUS P_{O_2} AND P_{CO_2} MONITORING

Oxygen and carbon dioxide diffuse through well-perfused skin from the superficial capillary network and can be measured using modified polarographic and glass electrodes respectively. The electrodes are heated to 43–45°C to arterialise the capillary blood and maximise capillary blood flow. Under optimal conditions, there is good correlation between arterial and transcutaneous gas tensions. Hence continuous monitoring of blood gas tensions is possible in a non-invasive way. The Ptc O_2 (transcutaneous)–Pa_{O_2} gradient and the output of the heating element have been used as indices of microcirculation. The accuracy of these devices is mainly confined to the neonatal period.

DRUG INFUSIONS

All drugs used in the care of critically ill children, including those used for cardiovascular support, should be administered according to body weight; accurate delivery is crucial. Accurate drug infusions require accurate devices, of which syringe pumps are the most useful. Potentially lethal errors in calculating drug dilutions are minimised by the use of dose/dilution/infusion rate guidelines that should be agreed upon within an institution by pharmacy and paediatric intensive care collaboration.[16] It is safer, with fewer drug errors and communication errors, time saving and potentially cost saving to have infusions made up in the same way by all referring institutions within the PICU network. These should be disseminated to referral institutions by the PICU and agreed at a clinical, clinical governance and management level.

PAIN RELIEF AND SEDATION IN CHILDREN

Management of pain and agitation in children has received inadequate attention and has tended to be underestimated and under-rated. Infants and children are often unable or unwilling to complain of pain. In the past, some believed that the neonate could not perceive pain.[17] It is now clear that neonates possess all the anatomical and neurochemical systems necessary for pain perception and exhibit physiological and behavioural responses to pain. Stress responses associated with pain and agitation may increase morbidity and

mortality in critically ill patients. Analgesia can be provided by narcotic infusions, local blocks and regional techniques in children of all ages. Painful procedures in the PICU must always be accompanied by appropriate analgesia. Sedative agents can reduce agitation and minimise harmful stress responses; however, all opiates and benzodiazepines may result in withdrawal reaction after discontinuation and attempt should be made to wean agents to a minimum once noxious procedures have been completed. Agents like oral or intravenous cloinidine[18] are useful as opiate-sparing and benzodiazepine-avoiding adjuncts, with minimal withdrawal effects on discontinuation. Having parents at the bedside for most of the child's waking day, distraction with play therapy, reading and videos, and appropriate surroundings including noise and light levels all help to alleviate children's anxiety, and do not come at the cost of withdrawal.

OUTCOME OF PAEDIATRIC INTENSIVE CARE

Depending on admission criteria, mortality in paediatric ICUs ranges from 5 to 15%.[19] If patients with pre-existing severe disabilities are excluded, the majority of survivors have a normal or near-normal life expectancy. A number of scoring systems have been developed or modified for paediatric application to predict ICU mortality. These scoring systems allow comparison between different ICUs, internal audits, stratification of patients for research purposes and analysis of cost–benefit. The Paediatric RISk of Mortality (PRISM) score[20, 21] and the Paediatric Index of Mortality (PIM) score[22] are applicable to a wide range of critically ill infants and children. Although PRISM performs marginally better, PIM is easier to collect and hence less prone to errors in data collection. PIM also has the advantage that it predicts mortality based on admission parameters whereas PRISM is based on the worst variables in the first 24 hours. In many paediatric ICUs, deaths occur within the first 24 hours. PRISM is often recording the dying process rather than predicting it. Specialised scores have been developed for specific problems, e.g. the Modified Injury Severity Scale (MISS) and Paediatric Trauma Score (PTS) for paediatric trauma, and the modified Glasgow Coma Scale (GCS) for neurological insults. Numerous scoring systems have been developed for meningococcaemia, the best validated being the Glasgow Meningococcal Septicaemia Prognostic Score (GMSPS).[23]

Compared with adult intensive care, children with equivalent Therapeutic Intervention Scoring System (TISS) scores have a lower in-hospital and 1-month mortality.[16] Although multiple organ failure increases mortality, the prognosis is considerably better than for adults.[24] There is evidence that mortality is lower in specialist paediatric ICUs[25] and that paediatric ICUs with a larger workload have better outcomes than those looking after fewer children.[26] General hospitals should therefore have facilities for urgent resuscitation of children prior to early transport to a specialised paediatric ICU. Unless unavoidable, critically ill children, particularly those requiring mechanical intervention, should not be cared for in an adult ICU for longer than 24 hours. The American Academy of Pediatrics, the Society of Critical Care Medicine, the British Paediatric Association and the Australian National Health and Medical Research Council have all stated that children should receive intensive care in specialist paediatric units.

Upper airway obstruction in children

Paul James and Sara Hanna

Upper airway obstruction is a particular clinical challenge in the paediatric population. The physics of air flow, the relative narrowness of the paediatric airway combined with the high rate of oxygen consumption in the child can produce rapid and unexpected deterioration in the clinical condition of a child. Moreover, severe airway obstruction occurs infrequently in non-specialist centres, but will require immediate intervention by the team present to secure a safe airway and maintain oxygenation. Successful management relies on an understanding of the paediatric airway, knowledge of the symptoms and signs that suggest unusual diagnoses or life-threatening obstruction, a realisation of what can and cannot be diagnosed without endoscopy and meticulous attention to basic anaesthetic principles.

ANATOMICAL AND DEVELOPMENTAL CONSIDERATIONS

The upper airway technically extends from the nares to the junction of the larynx with the trachea. It includes the nose, the paranasal sinuses, the pharynx and the larynx. It changes in size, shape and position from the neonatal period through infancy and childhood to resemble the adult airway by the age of 8 years.[1]

Children have a proportionally larger head and occiput relative to body size. The large head forces the neck into flexion when supine, which is a potential cause of airway obstruction.

NOSE

The nose is made up of nasal bones, nasal part of the frontal bones and frontal processes of the maxillae. The septum divides the cavity into two with the exterior opening at the nares and the opening into the nasopharynx at the choanae.

If the membrane that separates the palatal processes during development does not rupture the neonate will have choanal atresia and will present with airway obstruction.

Infants are obligate nasal breathers and secretions, oedema and blood easily block the small nasal apertures.

Similarly cellulitis, oedema or abscess formation in the paranasal sinuses will lead to airway obstruction.

PHARYNX

The pharynx forms the common upper pathway of the respiratory and alimentary tracts. It is divided into three regions: the nasopharynx, oropharynx and laryngopharynx, which open into the nasal cavity, mouth and larynx respectively.

The pharyngeal isthmus separates the nasopharynx and oropharynx. It closes off during swallowing.

The adenoids lie on the roof and posterior wall of the nasopharynx. These atrophy with age, but enlargement in early childhood may obstruct breathing. They may also be dislodged during instrumentation of the nose.

The oropharynx extends from the soft palate to the tip of the epiglottis. It is attached anteriorly to the base of the tongue via the glossoepiglottic folds, between which lies the valleculae.

At the entrance to the oropharynx is a collection of lymphoid tissue known as Waldeyer's ring. This consists of the lingual tonsil at the base of the tongue and bilateral palatine tonsils as well as the adenoids and tubal tonsils. Inflammation, infection or invasion of this tissue may obstruct breathing. The shape and dimension of the oropharynx affect airway function particularly during sleep.

The relatively large tongue decreases the size of the oral cavity and more easily obstructs the airway. Decreased muscle tone also contributes to passive obstruction of the airway by the tongue.

The laryngopharynx extends from the tip of the epiglottis to the lower border of the cricoid cartilage. The larynx bulges back into the centre of the laryngopharynx leaving a recess on either side known as the piriform fossa. This is a common site for impaction of swallowed foreign bodies.

LARYNX

The larynx is situated between the pharynx and trachea, extending from the base of the tongue to the cricoid cartilage.

The larynx consists of the thyroid cartilage, the cricoid cartilage, the paired arytenoids and the epiglottis, together with the small corniculate and cuneiform cartilages.

The laryngotracheal tube forms from the ventral wall of the foregut. The primitive glottis is formed at 10

weeks' gestation when the true vocal cords split. Failure of this process results in a congenital laryngeal web or atresia of the larynx. Incomplete division of the embryonic foregut results in a tracheo-oesophageal fistula.

The cricoid cartilage is shaped like a signet ring with the widest portion lying posterior. This is the only complete cartilage ring in the respiratory tract and is the narrowest portion of the larynx. Any oedema, infection or inflammation at this level results in airway compromise. Acquired subglottic stenosis as a result of prolonged or repeated tracheal intubation also occurs at this level. The larynx lies more anteriorly and higher, being at the level of the 4th cervical vertebra at birth, the 5th cervical vertebra at 6 years and the 6th cervical vertebra in the adult.

The epiglottis is a leaf-shaped structure attached to the posterior border of the thyroid cartilage by the thyroepiglottic ligament. The infant epiglottis is narrower, softer and more horizontally positioned than in the adult.

The more superior location of the larynx in children may create difficulty in visualising the laryngeal structures because of the acute angulation between the base of the tongue and the laryngeal opening.

The vocal cords are innervated by the recurrent laryngeal nerve, which if damaged results in paralysis of the corresponding vocal cord, causing it to lie motionless in the midline and at a lower level than the opposite side. Bilateral paralysis results in complete loss of voice and the two vocal cords may then flap together causing a valve-like obstruction during inspiration.

The highly compliant and poorly developed cartilage leads to increased susceptibility to dynamic airway collapse in the presence of obstruction. Loss of muscle tone in the pharynx leads to airway obstruction at the level of the soft palate and epiglottis. Laryngomalacia is a congenital abnormality of the larynx and results from the laryngeal structure being more pliable and less rigid than in the adult.[2]

PATHOPHYSIOLOGY

Resistance to laminar air flow increases in inverse proportion to the fourth power of the radius (Poiseuille's law) resulting in a marked increase in resistance to air flow with airway narrowing. The perpendicular cartilaginous ribs, which reduce the effect of the 'bucket handle' movement of the rib cage, and the immature intercostal muscles result in a mechanical 'disadvantage' and children are more reliant on the diaphragm for inspiration. Signs of increased respiratory effort to overcome airway obstruction include head bobbing (use of neck muscles), subcostal and sternal recession, tracheal tug and forced expiration (abdominal muscle contraction in expiration). Chronic airway obstruction may lead to chest wall deformity.

A higher metabolic rate and oxygen consumption, together with a smaller functional residual capacity and fewer fatigue-resistant fibres in the diaphragm, means there is little respiratory reserve and children with airway compromise can deteriorate very quickly.

However, children with chronic obstruction may manage surprisingly well with 'tolerable' airway noises and increased levels of respiratory work. Acute changes in airway calibre in these children may cause precipitous deterioration with accompanying hypoxia.

CLINICAL PRESENTATION

Stridor is a harsh, vibratory sound produced by turbulent air flow and is the cardinal feature of upper airway obstruction. Symptoms and signs vary with the level of obstruction, the aetiology and age of the child.

When faced with a child with possible airway obstruction the clinician must decide whether investigation and intervention are necessary and, if so, in what time scale. Very few diagnoses are truly clinical as it is only on direct endoscopy that the true cause of the problem can be confirmed. However, a careful history and examination are key to the decision-making process. Features that suggest obstruction needing urgent evaluation include episodes of colour change (pallor, cyanosis), apnoea, biphasic stridor, stridor when asleep and stridor from birth.

Extrathoracic obstruction is more pronounced during inspiration as the negative intraluminal pressure causes further airway narrowing. Obstruction is characterised by stridor and prolongation of inspiration. Intrathoracic airway diameter increases on inspiration and signs and symptoms occur mainly on expiration. There is prolonged expiration, wheeze and air trapping as seen in asthma, a common misdiagnosis.

Biphasic stridor is characteristic of mid-tracheal lesions or impending complete obstruction at any level (**Fig. 104.1**).

AETIOLOGY

The aetiology may be classified in a number of ways including according to the site of obstruction (i.e.

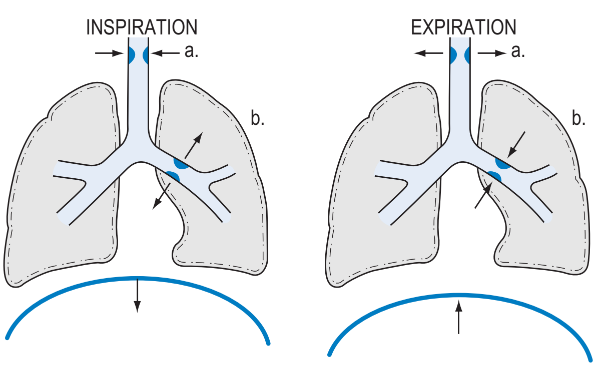

Figure 104.1 Dynamics of (a) extrathoracic and (b) intrathoracic airways obstruction.

Box 104.1 Common causes of upper airway obstruction in neonates/infants

Nose
- Choanal atresia

Oral cavity
- Encroachment of tongue on airway
- Macroglossia: Beckwith–Wiedeman, hypothyroidism
- Micrognathia: Pierre–Robin syndrome
- Haemangioma or venous/lymphatic malformation of tongue

Laryngeal abnormalities
- Laryngeal atresia
- Laryngomalacia
- Vocal cord paralysis
- Laryngeal cleft

Subglottic abnormalities
- Subglottic stenosis – congenital or acquired
- Subglottic haemangioma

Extrinsic lesions
- Mediastinal masses
- Cystic hygroma
- Foregut malformations
- Vascular abnormalities including rings and slings

nose, pharynx or larynx), whether it is congenital or acquired, or whether it is due to infection, malignancy, trauma, etc.

Boxes 104.1 and **104.2** list the more common causes according to the age of the child.

Box 104.2 Common causes of upper airway obstruction in children

Oral cavity

Encroachment of tongue on airway
- Macroglossia: Beckwith–Wiedeman, hypothyroidism
- Micrognathia: Pierre–Robin syndrome
- Haemangioma or venous/lymphatic malformation of tongue

Other oral mass lesions
- Ectopic–lingual thyroid/thyroglossal duct cyst/dermoid cyst/ranula

Nasopharynx/oropharynx/retropharyngeal space
- Adenoid/tonsillar inflammation and abscess
- Lymphatic malformation
- Supraglottitis
- Foreign bodies
- Trauma/burns
- Neoplasms

Larynx/cervical trachea

Supraglottic
- Laryngomalacia
- Epiglottitis

Glottic abnormalities
- Vocal cord paralysis
- Laryngeal cleft
- Recurrent respiratory papillomatosis

Subglottic abnormalities
- Croup
- Subglottic stenosis
- Congenital
- Acquired (prolonged or traumatic intubation)
- Subglottic haemangioma

INFECTIONS OF THE UPPER AIRWAY

Viral and bacterial infections causing upper airway obstruction present in a very similar way and are often concurrent. A logical and useful approach to diagnosis is to identify the site of infection and consider the nature of the condition.[3]

PHARYNGEAL INFECTIONS

In the pharynx the site of infection is the peritonsillar bed in 49% of cases, the retropharyngeal space in 22% of cases and the parapharyngeal spaces resulting in abscess formation in 2%.[4]

Bacterial tonsillitis and peritonsillar abscess (quinsy)

Tonsillitis is caused by the aerobes *Streptococcus pyogenes*, *Streptococcus pnemoniae* and *Staphylococcus aureus* and the anaerobes *Fusobacterium* spp., *Prevotella* spp., *Porphyromonas* spp. and *Actinomyces* spp. Aerobes predominate in the acute primary infection, whereas anaerobes are associated with abscess formation or extension across tissues. Treatment is with third-generation cephalosporins or co-amoxyclav as there is a high incidence of penicillin resistance.[5]

Metronidazole or carbapenems should be added if there is extension or abscess formation. Clindamycin or linezolid should be added to reduce bacterial exotoxin release if toxic shock is suspected.

Surgical removal in the acute setting is controversial as there is potentially an increased risk of bleeding, but if there is pus then drainage is indicated to prevent spontaneous rupture.[6]

Infectious mononucleosis

Infectious mononucleosis is caused by the Epstein–Barr virus.

Airway obstruction can occur and, despite steroids, 40–88% of patients with airway obstruction require tonsillectomy.[7]

The use of steroids does reduce duration of fever, pharyngitis and abnormal haematological findings.[8]

Retro- and parapharyngeal abscess

Retropharyngeal abscesses are more common in boys (ratio 2:1) and occur at a median age of 3 years. The incidence appears to be rising.[9]

The principal symptoms are fever, sore throat, trismus, torticollis, neck swelling and pain. Airway obstruction is rare.[10]

Staphylococci and streptococci are the usual causal agents but growth is often polymicrobial and treatment is with broad-spectrum antibiotics. Surgical drainage is indicated if there are symptoms persisting for 2 days or more, prior administration of antibiotics, and fluid on computed tomography scan with a cross-sectional area of >2 cm^2. Complications include mediastinitis and Lemierre's syndrome.

Lemierre's syndrome

Described in 1936, Lemierre's syndrome occurs when a pharyngeal/tonsillar infection is complicated by thrombophlebitis and septic emboli. The organism is usually *Fusobacterium necrophorum*. Local effects classically include thrombosis in the ipsilateral internal jugular vein and more distant spread with suppuration most commonly affecting the lungs, but also causing septic arthritis, osteomyelitis, meningitis and liver, renal and skin abscesses.[11]

Ludwig's angina

Ludwig's angina is a diffuse infection of the submandibular and sublingual spaces. Severe pain, fever, malaise and dysphagia occur with swelling that can be large enough to cause airway compromise. Antibiotic choice is as for tonsillar abscess and surgical drainage is indicated if there is pus formation.[12]

LARYNX/TRACHEAL INFECTIONS

Croup

Croup (laryngotracheobronchitis) is common and usually caused by the virus parainfluenza, influenza type A or B, respiratory syncytial virus or rhinovirus. It is the commonest cause of acquired acute stridor in children and is a clinical diagnosis. There is a sudden onset of a seal-like barking cough usually accompanied by stridor, hoarse voice and respiratory distress. Symptoms are usually worse at night. It commonly affects children age 6 months to 3 years with a peak incidence at 2 years. Only 2% of cases are admitted to hospital each year, of which only 0.5–1.5% will require intubation.[13]

A Cochrane review investigated the use and effectiveness of steroids in the treatment of children with croup and recommended all children should receive either dexamethasone 0.15 mg/kg or prednisolone 1–2 mg/kg orally.[14]

Nebulised epinephrine (adrenaline) 1/1000, 0.5 mL/kg to a maximum of 5 mL may be used to reduce airway swelling acutely in severe croup. This is a short-term measure and may allow time for the steroids to work or experienced personnel to be called to the child. It may be repeated if necessary after 30–60 minutes, but further doses should be used with caution as repeated need suggests an extremely narrow airway.

If intubation is indicated visualisation of the larynx should not be a problem; however, a smaller tracheal tube than normal for the age is usually required because of subglottic oedema. Once the obstruction is bypassed most children can be managed on a Swedish nose with minimal sedation and arm splinting. Extubation may be attempted after 72 hours (or earlier if a large leak develops). Around 10% will require re-intubation.

Epiglottitis

Very few clinicians have seen epiglottitis since the introduction of *Haemophilus influenzae* type B vaccination in 1992. In children, it is still almost always due to infection with *H. influenzae* type b (Hib), although it can be caused by beta-haemolytic streptococci, staphylococci or pneumococci. In a recent retrospective study, 10% of children presenting with epiglottitis were found to have Hib infection, despite having being vaccinated.[15]

It occurs usually in children aged 2–6 years, with a peak incidence at 3 years.

Epiglottitis is painful. There is an abrupt onset of high fever, sore throat, dysphagia, soft stridor and drooling. The child may prefer to sit leaning forwards with mouth open.

The key to management is to secure the airway under inhalation anaesthesia with an ENT surgeon standing by if a tracheostomy becomes necessary. Visualisation of the laryngeal inlet may be difficult. A bacterial swab of the epiglottis should be taken once the airway is secure. Antibiotic treatment with an extended-spectrum cephalosporin (e.g. ceftriaxone) is indicated. Recovery usually occurs about 48 hours after the institution of antibiotic therapy and confirmed by visualisation of a normal epiglottis on laryngoscopy.

Bacterial tracheitis

Bacterial tracheitis is uncommon. The condition may occur at any age. The usual pathogens are *S. aureus*, *H. influenzae*, streptococci, and *Neisseria* species.[16]

The signs and symptoms of bacterial tracheitis are frequently intermediate between those of viral croup and epiglottitis. Coughing produces copious tracheal secretions and retrosternal pain. The voice may be hoarse and stridor prominent. The larynx, trachea and bronchi can become acutely obstructed with purulent debris and inflammation with adherent pseudomembranes overlying friable tracheal mucosa.

Most patients with bacterial tracheitis will require tracheal intubation.

At laryngoscopy, the epiglottis and supraglottic structures will appear normal, although slough and pus may be visible beyond the vocal cords. Significant pneumonia and systemic symptoms of bacterial septicaemia are not unusual. Ceftriaxone is a reasonable first-line antibiotic therapy. The average duration of tracheal intubation is 6–7 days and antibiotic therapy and hospitalisation may be required for up to 14 days.

Diphtheria

Diphtheria is caused by *Cornyebacterium diphtheriae* and *Cornyebacterium ulcerans*. It begins with a croup-like

illness, cough and sore throat, but often progressing to death through sepsis, suffocation by the ‘pseudomembranes’ of serocellular exudate and direct effects of the powerful exotoxin, which has an affinity for neural endings (paralysis), cardiac muscle (heart block and myocardial failure) and the adrenal glands (hypotension with endocrine failure). Unless there is a high index of suspicion, it is a diagnosis easily missed. Treatment includes administration of specific antitoxin and appropriate antibiotics.

Respiratory papillomatosis

Respiratory papillomatosis is characterised by recurrent proliferations of squamous papillomata within the airway, anywhere from lips to lungs. The viral pathogen is most commonly human papilloma virus types 6 and 11. The recurrent nature of this condition often necessitates multiple surgical procedures. The current management philosophy is toward a more conservative approach, aimed at ameliorating airway symptoms while limiting subsequent scarring of the larynx. Surgical debulking is the treatment of choice and several modalities have been used, including ‘cold steel’, microdebrider, CO_2 laser and radiofrequency ablation.

The use of adjuvant medical treatments, such as intralesional cidofovir remains controversial.[17]

TRAUMA

INHALATIONAL BURNS

Inhalational injury should be suspected with burns occurring in a closed space, and when facial burns, singed nasal hairs and oropharyngeal carbonaceous material are present. Respiratory complications are the major cause of mortality in children who are burnt. Direct airway burns or inhalation of products of combustion may lead to rapidly progressive oedema. The situation may be compounded by small airway and lung injury and by the need to provide adequate analgesia. Early intubation is strongly recommended prior to an emergency situation developing. Tracheal tube fixation is critical and may be problematic with extensive facial burns; it may require suturing of the tube to the nasal septum or securing the tube to the teeth.

FOREIGN BODY ASPIRATION

Foreign body aspiration is one of the leading causes of death in children. It is most common in those under 3 years, but can occur at any age.[18] Most deaths occur at the time of aspiration due to complete upper airway obstruction. Of those children who reach hospital, the mortality is low.[19] The most common aspirated object is ‘food’, usually nuts. Peanuts account for one-third of all foreign body aspirations.

Often the inhalation event is not witnessed, and the history may be less clear than expected. Presentation varies from severe acute upper airway obstruction through to a well, pink child with a persistent cough.

More than 90% of foreign bodies lodge below the upper airway in a main bronchus, slightly more commonly on the right side in children.[20]

As the majority of inhaled material is organic in origin a plain radiograph may fail to demonstrate an abnormality – especially in the first 24 hours, although X-rays in inspiration and expiration may show evidence of gas trapping.[18]

Management is as per the ‘choking child’ basic life support algorithm. Children with effective cough should be closely observed and encouraged to cough by themselves. If the cough is not effective and the child is conscious, the rescuer may intervene with five back blows followed by five chest thrusts (or abdominal thrusts in older children).

If the child is not conscious, the child should have airway, breathing and circulation assessed and managed as per the basic life support guidelines, with assisted ventilation and chest compressions.

Most children who reach hospital with an inhaled foreign body, or possibility of such, should have a rigid bronchoscopy under general anaesthesia.[21]

Most anaesthetists will use an inhalational induction with sevoflurane in order to maintain spontaneous ventilation.

N_2O is avoided particularly if there is radiological evidence of gas trapping. The cords and upper trachea are sprayed under direct laryngoscopy with 4 mg/kg lidocaine. Maintenance of ventilation and oxygenation during rigid bronchoscopy in children is controversial. The options are a spontaneously breathing technique (reduces the chance of distal movement or dislodgement of the foreign body) or muscle relaxation and use of positive-pressure ventilation (reduces atelectasis and desaturation episodes). It is difficult to demonstrate the superiority of one technique over another.[19]

SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital or acquired (usually due to post-intubation laryngeal injury).

The main feature is chronic, inspiratory stridor often made worse by intercurrent viral respiratory tract infection. When a child presents acutely the management is as for croup. However, ENT referral is necessary for diagnosis and management. The surgeon will grade the severity of the stenosis according to the size of endotracheal tube that can pass relative to that expected for age. This assessment and clinical condition will inform the decision to intervene.[22]

Treatment is laryngotracheal reconstruction (LTR) whereby a cartilage graft, from either the costal cartilages or the thyroid cartilage, is inserted into a vertical laryngotracheal fissure in order to expand the stenotic segment. Some stenoses will also require a posterior graft inserted into a posterior cricoid chondrotomy. In a double-stage LTR a tracheostomy is inserted to safeguard the airway postoperatively and the grafted area

is stented for approximately 6 weeks. A further procedure is then performed to remove the stent and assess the airway. A tracheostomy is not used in a single-stage LTR and the child is left intubated with an age-appropriate endotracheal tube for 5–7 days postoperatively, both stenting and safeguarding the airway. All patients receive anti-reflux medication postoperatively to negate the negative impact of gastric contents on mucosal healing.

CONGENITAL

PIERRE ROBIN SEQUENCE

Pierre Robin sequence is a congenital anomaly presenting with micrognathia, glossoptosis and a cleft palate. Although there is a spectrum of airway obstruction most children can be managed by conservative measures or with a nasopharyngeal airway (NPA) for a few months. The natural history shows that, with normal growth, airway compromise resolves without immediate surgical intervention as previously advocated. However, a few children do require tracheostomy.[23]

CYSTIC HYGROMA

Conspicuous at birth, cystic hygroma or lymphangioma is a relatively rare cause of upper airway obstruction in infancy. The tumours consist of masses of dilated lymphatic channels. They usually occur in the neck but may involve tissues of the tongue and larynx and occasionally extend into the mediastinum. Airway obstruction may be due to infection or haemorrhage into the lesion. Surgical excision has been the mainstay of treatment, although complete removal is difficult and recurrence is common. Although some authors have reported watchful waiting of cystic hygroma, it should be considered only in patients who are asymptomatic. The medical treatment consists of the administration of sclerosing agents.

LARYNGOMALACIA

Laryngomalacia is the commonest cause of congenital stridor and usually presents within the first 2 weeks of life. Clinicians should not give this diagnosis without full airway assessment to any baby with life-threatening symptoms or stridor that is obvious at birth. Airway obstruction results from collapse of supraglottic structures on inspiration, and expiratory symptoms are not a feature. Stridor often gets worse initially for 6–9 months before gradually improving, with most children being free of symptoms by 18–24 months.[24]

It is a dynamic condition and the supraglottic collapse is most obvious during the ‘waking phase’ of anaesthesia if a formal airway assessment is done.

The majority of children will not require surgical intervention, but the remaining 5–10% require some form of surgical treatment. Surgical options include division of the aryepiglottic folds to ‘open’ the constricted supraglottis, resection of the redundant mucosa and suspension of the prolapsing epiglottis to uncover the laryngeal introitus. A degree of gastro-oesophageal reflux disease (GORD) is often associated with laryngomalacia and all children should therefore receive anti-reflux medication. This possibly reflects changes in airway and intrathoracic pressures in response to the airway obstruction, as opposed to being a causal factor. A neurological form of the condition exists and may be seen in children with neurological or neuromuscular conditions, such as cerebral palsy. In such cases, surgical intervention should be approached with caution and it may be most appropriate to manage severe airway collapse with a tracheostomy.[25]

OTHER

INFANTILE HAEMANGIOMA

Infantile haemangiomas are the most common tumours of infancy, affecting approximately 1 in 10 children.[26] These are highly proliferative vascular tumours that may grow very quickly, causing obstruction when the airway is involved; if these are left untreated there is a 50% mortality rate. Most airway haemangiomas will coexist with cutaneous lesions (but not vice versa).[27] The PHACES syndrome comprises airway haemangiomas with associated deep or diffuse cutaneous, segmental haemangiomas as well as posterior fossa malformations, arterial anomalies, cardiac/aortic defects, eye anomalies and sternal defect.[28]

Medical and surgical interventions have included steroids, chemotherapeutic agents (vincristine, interferon-α), laser treatment, surgical excision, tracheostomy, or a combination of these, but the spectacular effect of propranolol on cutaneous haemangiomas of infancy was described for the first time in 2008[29] and confirmed by a meta-analysis as being the best treatment available for infantile haemangiomas.[30] The mean dose of propranolol was 2 mg/kg/day (range 0.5–3 mg/kg/day). The mean treatment duration was 6 months (range 1.5–10 months). Clinical improvement was seen in a range of 24 hours–3 weeks (mean 3.8 days). Complications related to propranolol usage were found in one child (2.94%) who developed bronchoconstriction during the first week of treatment.

Because of the possible side-effects of propranolol, current infantile haemangioma treatment centres recommend that a full cardiovascular and respiratory review be performed prior to initiation of therapy.

VOCAL CORD PALSY

Vocal cord palsy may be idiopathic, a result of a neurological abnormality, or traumatic (birth or iatrogenic).[31] It may be uni- or bilateral.

Unilateral palsy presents with stridor and dysphonia, which often resolves with time as the contralateral vocal cord compensates.

Bilateral vocal cord palsy is potentially life threatening and a tracheostomy may be necessary in approximately half of cases. Magnetic resonance imaging of the brain is mandatory in order to exclude an Arnold–Chiari malformation with hydrocephalus.[32] Spontaneous recovery rates of up to 70% are reported.[31]

ANAESTHESIA FOR RELIEF OF UPPER AIRWAY OBSTRUCTION

The principle behind safe induction of anaesthesia in the obstructed airway is the maintenance of spontaneous ventilation. Muscle relaxants should be avoided before the airway is secure in order to avoid the potentially disastrous 'can't intubate, can't ventilate' scenario.

A gaseous induction using 100% oxygen with either sevoflurane or halothane is the technique of choice. The aim is to attain a plane of anaesthesia that is deep enough to allow laryngoscopy, but this is a slow process. If the airway becomes obstructed following loss of consciousness, it can be improved by applying CPAP, changing the patient's position (lateral or semiprone position), using simple airway manoeuvres or simple airway adjuncts such as a nasal airway.

Sufficient depth of anaesthesia for laryngoscopy may not be achieved because of the obstructed airway. A laryngeal mask airway may help. If it is impossible to secure the airway then direct access to the trachea via a cricothyroidotomy or tracheostomy should be gained.

Important points are:

- A prepared induction should be undertaken with efficient suction apparatus, a range of tracheal tubes, suitable stylets, bougies, trained staff, full monitoring, etc.
- Induction in the adopted position, for example sitting in epiglottitis, is advocated. The child is laid flat after induction and prior to intubation.
- Care must be taken not to distend the stomach as this will compound difficult ventilation.
- Orotracheal intubation is quickest and safest, and should be performed initially. After adequate tracheal suction, the tube is changed to a nasotracheal one. Muscle relaxants may be used at this point if the operator is confident of the ability to intubate and/or ventilate.[33]

CARE OF THE SECURED AIRWAY

Successful management of upper airway obstruction in children requires optimal care of the nasotracheal tube. Such children must always be nursed in an ICU with adequate nursing ratios. The nasotracheal tube must be positioned at the level of the clavicular heads (T_2) on chest X-ray. A meticulous technique of fixation must be employed to prevent accidental extubation. Adequate humidification is important to prevent obstruction of narrow tubes by secretions.

Repeated suctioning of secretions is required. Instillation of saline (0.5–1.0 mL) prior to suction may be necessary to encourage removal of secretions. Light sedation is used to improve tolerance of the tracheal tube and to reduce the risk of self-extubation. Arm restraints may also be advisable, particularly in very young children.

In the event of clinical deterioration after intubation, a simple mnemonic may aid successful management; DOPES represents *d*isplacement of the tube, *o*bstruction of the tube, *p*neumothorax, *e*quipment failure and *s*tomach distension.

A true 'can't intubate or ventilate' scenario is rare in children. More often the situation has arisen due to 'operator error' for example suboptimal positioning of the child, inadequate anaesthesia, a distended stomach, a blocked endotracheal tube or understandable panic. However, the only objective in this situation is to maintain oxygenation and if none of the basic manoeuvres resolves the situation the options are to perform a needle cricothyrotomy or a formal tracheostomy.

TRACHEOSTOMY

Tracheostomy remains a life-saving procedure and must be undertaken if tracheal intubation is impossible. It is best performed under general anaesthesia with the neck extended. The airway can be maintained by facemask or laryngeal mask airway. Tracheostomies have been formed under local anaesthesia.

Care of a newly created tracheostomy is similar to that of an endotracheal tube, with the additional problem of some discomfort and the likelihood of fresh blood in the airway. Stay sutures in the tracheal wall lateral to the incision aid recannulation if accidental dislodgement occurs prior to formation of a well-defined tract.

The first tracheostomy tube change is undertaken once a tract has been established, usually between 5 and 7 days.

NEEDLE CRICOTHYROIDOTOMY

Cricothyroidotomy is the creation of an opening in the space between the anterior inferior border of the thyroid cartilage and the anterior superior border of the cricoid cartilage, to gain access to the airway below the glottis. It is difficult and risky in a small child. There are purpose-made paediatric kits available and these should be immediately available in every paediatric anaesthetic room.

Newer cannulae have both a 15 mm and a Luer-lock connector. It is not possible to ventilate a patient with a self-inflating bag via a needle cricothyrotomy

and the cannula should be connected via the Luer-lock connection to an oxygen flowmeter via a Y-connector. The oxygen flow rate is initially set at the child's age in years. Ventilation occurs by occluding the open end of the Y-connector with a thumb for 1 second. If this does not cause the chest to rise, the flow should be increased by increments of 1 L/min.

Expiration must occur via the upper airway, even in situations of partial upper airway obstruction. If upper airway obstruction is complete, the gas flow must be reduced to 1–2 L/min. This will provide some oxygenation but little ventilation. Insufflation will buy a little time in which to secure a surgical airway. Complications include bleeding, pneumothorax, pneumomediastinum, subcutaneous emphysema, tracheo-oesophageal fistula, infection, haematoma and catheter dislodgement.

The recent national audit of major complications of airway management in the UK showed that the 'can't intubate, can't ventilate' scenario is rare in paediatric practice. Cricothyroidotomy and jet ventilation is difficult and risky, with the only reported attempt being unsuccessful. Tracheostomy by an ENT surgeon was used successfully more frequently.[34]

Acute respiratory failure in children

Tavey Dorofaeff and Kevin Plumpton

Acute respiratory failure in children, as in adults, is a failure of gas exchange – inadequate oxygenation and/or carbon dioxide clearance. Respiratory distress refers to both the sensation of breathlessness and the signs of increasing effort to breathe as a consequence of deteriorating gas exchange (**Box 105.1**).[1,2]

EPIDEMIOLOGY

Established or imminent respiratory failure is the commonest reason for admission to a neonatal intensive care unit (NICU) or paediatric intensive care unit (PICU). There were approximately 9200 paediatric admissions to Australian and New Zealand intensive care units in 2011 (adult ICUs and PICUs). Of these, approximately 53% had invasive ventilation. Respiratory disease as the lead diagnosis was the single commonest reason for admission (2661 patients ~29%). Infants between 1 and 12 months of age make up the largest majority with just over 1000 admissions per annum. There is a peak of admissions for respiratory diagnoses during the winter months that is predominantly due to acute viral bronchiolitis. Bronchiolitis makes up 12.9% of all non-elective ICU admissions in children. Mortality due to respiratory disease occurs in 1.9% of all paediatric admissions to ICU, representing 17.1% of paediatric deaths in ICUs around Australasia (ANZPIC unpublished data 2010/2011).

VENTILATORY DISADVANTAGES OF CHILDREN

Neonates and small infants have a higher resting metabolic requirement for oxygen – estimated to be 7 mL/kg/min compared with 4 mL/kg/min for a school-age child or adult. Small infants are primarily diaphragmatic breathers with a compliant rib cage that makes for less efficient mechanics of breathing. The resultant reduced intrapleural pressure of –1 to –2 cm means there is less distending pressure applied to the lung. At end-expiration infant lung volumes approximate their functional residual capacity. This means less reserve and a tendency to collapse airways and lung parenchyma. The respiratory musculature also has proportionately more fatigable muscle fibres than in older children.

In sickness, infants can increase their respiratory rate only to increase minute ventilation. Without the ability to increase tidal volume, which is commonly reduced in illness, infants and small children get into a downward spiral of decreased distended lung, further hypoventilation and further lung derecruitment.

The airways of a young child are also disproportionately smaller than an adult's. Any obstruction of the lumen of the airways with increased mucous production or bronchoconstriction also increases airways resistance to the fourth power of the radius (Hagen–Poiseuille equation: $\Delta P = 8\ \mu LQ/\pi r^4$). Hence, anatomically small airways are a distinct disadvantage.

This lack of lung reserve and tendency to hypoxia is vitally important when intubating a sick infant. Infants need to be artificially (manually) ventilated until intubation is attempted. A true 'rapid sequence' induction with no assisted ventilation post sedation and muscle relaxant is not achievable and will usually result in further deterioration so that assisted ventilation prior to intubation is almost always required.

SIGNS AND SYMPTOMS OF ACUTE RESPIRATORY FAILURE

Signs and symptoms of respiratory failure in children that indicate the need for an increasing level of respiratory support are not subtle and are usually apparent from a brief focused clinical exam of the respiratory system. They relate to the developmental changes that influence the ways in which children compensate for, or decompensate from, respiratory failure. Due to pulmonary mechanics neonates and small infants tend to become tachypnoeic, but can also develop apnoeas from early in an illness. They exhibit signs of intercostal, subcostal and tracheal tug when distressed. Mild cyanosis is generally well tolerated but extreme tachypnoea, deep cyanosis, relative bradypnoea or apnoea and bradycardia are all signs of serious compromise where respiratory support needs to be instituted immediately. It may or may not be possible to determine focal clinical signs on examination of the chest.

Infants and toddlers also compensate with tachypnoea to increase minute ventilation but do not tend to exhibit apnoea unless severely decompensated. Focal signs are easier to elucidate. As children become more

Box 105.1 Causes of respiratory failure in children

Common causes of respiratory failure in the neonate
Congenital
Respiratory distress syndrome of prematurity
Congenital heart disease
Laryngo/tracheo/bronchomalacia
Vascular rings and slings
Diaphragmatic hernia
Pulmonary hypoplasia
Gastroschisis and omphalocele
Neuromuscular and skeletal disorders
Acquired
Transient tachypnoea of newborn
Meconium aspiration syndrome
Neonatal pneumonia
Pulmonary haemorrhage
Diaphragmatic palsy

Common causes of respiratory failure beyond the neonatal period
Bronchiolitis
Pneumonia
Asthma
Croup
Tumours
Trauma
Acute-on-chronic respiratory failure with chronic neuromuscular conditions
Acute respiratory failure with acute neuromuscular conditions
ARDS
Respiratory failure related to immunocompromised host

upright and mobile they develop more of an adult body habitus. Signs and symptoms are similar to adult respiratory failure. By the time a child is a teenager the signs and symptoms parallel those in adult respiratory medicine.

PREMATURITY AND NEONATAL CHRONIC LUNG DISEASE

The lungs develop throughout the fetal period until late childhood. Lung development is divided into five stages: embryonic, pseudoglandular, canalicular, saccular and alveolar. The embryonic and pseudoglandular phases have very little gas exchange ability. At 28 weeks of gestation, the middle of the canalicular stage is where a significant amount of the ventilation can occur within the respiratory bronchioles; 28–32 weeks corresponds to the saccular stage. Alveoli are developing and surfactant production begins around 32 weeks and continues into childhood with increasing maturity of alveoli, replication and increasing numbers. Consequently children born at increasingly premature gestations and those of smaller size have increasing risk of severe lung disease. Factors such as infection, stress and exogenous steroids may influence the development of gas exchange tissues and of the production of surfactant. Underdevelopment of the lungs of the premature infant is only one of the issues that affect these infants. As a result they require a complex system of intensive care and aftercare as they are medically delicate for the first few years of life.

There is some relationship between prematurity and body weight. They are described as follows: a term newborn is delivered from 37 weeks after the mother's last menstrual period; prematurity occurs when a newborn is <37 weeks of completed gestation; extremely low birth weight is <1000 g, very low birth weight <1500 g and low birth weight is <2500 g.

Chronic neonatal lung disease (CNLD) is defined as either: oxygen requirement at 28 days post delivery (irrespective of premature gestation), or oxygen requirement at 36 weeks of gestational age. However, all premature infants will have some degree of abnormal lung development. Bronchopulmonary dysplasia and hyaline membrane disease are pathological findings on biopsy or autopsy of premature infants who have respiratory failure. They are often used synonymously to describe CNLD and respiratory distress syndrome. The pathological features of CNLD include alveolar septal fibrosis with alternating collapse and hyperinflation of acini. Smooth muscle hypertrophy/hyperplasia may also be present. Chest X-ray (CXR) may reveal generalised hyperinflation, multiple cystic areas and opacities. A novel type of CNLD exists (Wilson Mikity syndrome) where babies may not have an initial oxygen requirement but go on to develop an oxygen requirement towards term or beyond.

Complications of prematurity would be the most common reason for admission to a PICU for severe respiratory failure. This is frequently in the context of an acute viral chest infection. CNLD, airway reactivity and pulmonary hypertension exacerbate any symptoms the infant may have otherwise suffered, increasing the need for invasive and non-invasive respiratory support.

Apnoea is a feature of prematurity and is a common symptom of illness in premature infants from birth until about 3 months of corrected age. Important differentials include sepsis (bacterial and viral), intraventricular haemorrhage and pain. Respiratory stimulants such as caffeine can be used to treat apnoea. This is not always effective. Not infrequently, the infant may need non-invasive support such as continuous positive-airway pressure (CPAP) or bi-level positive-airway pressure (BiPAP) or ultimately invasive ventilation to manage the underlying condition and the apnoea. Central hypoventilation due to a *PHOX2B* mutation is increasingly recognised as a congenital form of depressed ventilatory drive beyond the neonatal period. It manifests as hypoventilation during sleep. These children usually need non-invasive or invasive support. If undiagnosed these children can present as sudden infant deaths.

Maternal tobacco use in pregnancy is a significant cause of prematurity and impairs lung development. Environmental tobacco smoke exposure exacerbates chronic lung disease, asthma and recurrent bronchiolitis in older infants.

LARYNGOMALACIA/TRACHEOMALACIA/BRONCHOMALACIA

This results from cartilaginous weakness of the larynx, trachea, main bronchi or any combination of these. This causes a 'floppy' airway that tends to collapse during inspiration and/or expiration. Minor respiratory illnesses can result in increased turbulent flow due to increased respiratory rate and significant dynamic airway obstruction. What might be a mild illness for a normal infant becomes one that may require ventilation for a child with malacia. Ventilator weaning is often troublesome in these infants. Severe long-segment malacia can be an indication for long-term non-invasive home ventilation or tracheostomy and invasive ventilation. Over the first 18–24 months of life there is growth of the cartilage and improvement in the airway rigidity.

Although malacia in the trachea may occur de novo, intrathoracic anomalies (congenital heart disease, tracheoesophageal fistula, etc.) or space-occupying lesions can affect the development and rigidity of the airways.

CONGENITAL HEART DISEASE

Many of the congenital cardiac lesions present with respiratory features. Close examination may or may not reveal congenital heart disease as a cause for the patient's illness. Although antenatal ultrasound scanning detects a significant number of lesions, early discharge or home birth means that symptoms can develop and not be appreciated until acute decompensation occurs.

Congenital heart lesions producing acute respiratory failure fall into four main groups:

- *Left heart obstruction (e.g. critical aortic stenosis, interrupted aortic arch and coarctation of aorta):* this leads to pulmonary oedema, reduced pulmonary compliance and respiratory failure.
- *Large left-to-right shunts (e.g. ventricular septal defect and patent ductus arteriosus):* excessive pulmonary blood flow can cause pulmonary oedema, airway compression and obstruction. Minor intercurrent infection results in decompensation. Correction of the defect improves lung mechanics.
- *Cyanotic lesions:*
  - there is obstruction to pulmonary blood flow (e.g. tetralogy of Fallot and critical pulmonary stenosis)
  - the pulmonary and systemic circuits are in parallel (e.g. transposition of the great arteries)
  - there is complete mixing of systemic and pulmonary blood (e.g. single ventricle and truncus arteriosus).

In lesions with reduced pulmonary blood flow, lung compliance is high. High-pressure ventilation may further impede pulmonary blood flow, leading to increased hypoxaemia. Lesions associated with increased pulmonary blood flow have problems of reduced lung compliance and air trapping (due to small airways and bronchial compression) in addition to hypoxaemia (due to mixing).

- *Vascular lesions:* these are associated with compression or stenosis of large airways (see below).

Early institution of intravenous prostaglandins in company with other supportive measures such as intubation, ventilation, judicious fluid therapy and inotropes will be life saving in these infants. There are no contraindications to the commencement of prostaglandins in a collapsed infant where a paediatric cardiologist is not available to make an immediate assessment. An exception is that, in total anomalous pulmonary venous drainage, prostaglandin use could make the cyanosis worse, but most likely will be ineffectual and can be stopped if cyanosis worsens. This diagnosis requires expert assessment not immediately available to many collapsed infants at their initial presentation.

VASCULAR RINGS AND SLINGS[11]

Vascular rings and slings may be considered complete or incomplete and result from aberrant vessels and the ductus arteriosis (or ligamentum arteriosis, if the duct is closed) leading to a constricting lesion of the trachea or bronchi. Obstruction requires surgical correction and tracheobronchomalacia often remains once the obstruction is relieved. The commonest type of sling is the pulmonary artery sling: an anomalous left pulmonary artery and the ductus encircling the trachea posteriorly. Vascular rings most commonly result from a right-sided aortic arch or a double aortic arch. There are a number of combinations: double aortic arch and derivatives causing complete ring, right-sided aortic arch and anomalous right subclavian artery, right-sided aortic arch, mirror image vessel branching and left ductus arteriosis, and an anomalous innominate artery.

CONGENITAL DIAPHRAGMATIC HERNIA (CDH)

There are two types:

BOCHDALEK HERNIA

A Bochdalek hernia involves a deficiency in the posterolateral part of the diaphragm. Most occur on the left side. A variable amount of the abdominal viscera herniates through into the chest. Presentation is dependent upon

whether the hernia is diagnosed antenatally or not and whether pulmonary hypoplasia and pulmonary hypertension are present. Antenatal diagnosis may allow for use of fetal intrauterine therapy; however, this is still experimental. The spectrum of clinical course ranges from profound, non-survivable hypoxia and pulmonary hypertension in the newborn to mild tachypnoea in infancy or an incidental finding diagnosed when a child comes to medical attention. Therapy involves respiratory support as appropriate and surgical closure of the defect. Children with severe respiratory failure may need extensive medical stabilisation with high-frequency oscillator ventilation (HFOV), nitric oxide therapy and extracorporeal life support (ECLS). Partial liquid ventilation has also been used in some centres. About 10% of children with CDH have a chromosomal abnormality.

MORGAGNI'S HERNIA

A Morgagni hernia is in the anterior diaphragm. Typically only bowel will herniate through the defect. It is extremely uncommon for this hernia to cause respiratory embarrassment. It is often an incidental finding or associated with mild respiratory disease. Clinically insignificant hernias are repaired electively.

PULMONARY HYPOPLASIA

This is usually secondary to a space-occupying lesion within the chest, which limits room for lung development and also results in abnormal pulmonary vasculature and pulmonary hypertension. Congenital diaphragmatic hernia, cystic adenomatous malformation, congenital neuroblastoma and great vessel abnormalities are common causes. Pulmonary hypoplasia can be idiopathic.

OMPHALOCELE AND GASTROSCHISIS

An omphalocele results from failed development of the abdominal wall musculature. The abdominal organs are contained within a protruding thin-walled peritoneal sac. There is a high incidence of associated abnormalities (50–70%) and chromosomal defects (30%). Gastroschisis is herniation of the small bowel (usually) through an ischaemic defect in the abdominal wall. Approximately 15% of these children have associated defects or chromosomal abnormalities. Neither abnormality causes respiratory failure. However, surgical reduction may lead to increased intra-abdominal pressure, which limits excursion of the diaphragm and ventilation of the lungs. This is more likely with an omphalocele as more abdominal viscera are exteriorised.

NEUROMUSCULAR AND SKELETAL DISORDERS

Any disorder that affects the ability of the muscles to 'drive' the ventilatory pump, or that causes a chest wall deformity, can compromise the effectiveness of ventilation. In the neonatal period these present with hypoventilation, desaturation and apnoea. Ventilator dependence as a neonate with these disorders indicates that the child is unlikely to survive without intensive support and, most likely, mechanical ventilation. Parents should be counselled appropriately. Spinal muscular atrophy (SMA) type 1 is the commonest example of this. Less severe neuromuscular disorders may survive the neonatal period but go on to develop respiratory failure later (e.g. Duchene's muscular dystrophy, SMA types 2 and 3). The amount of support offered needs to take into consideration ethical treatment, rational expenditure of resources and the wishes of the family and child (if appropriate).

ACQUIRED NEONATAL DISEASES

TRANSIENT TACHYPNOEA OF THE NEW BORN (TTN)

TTN is transient delayed clearance of fetal lung fluid. In transition from intrauterine life the infant has to aerate the majority of its alveoli within a few minutes. It is truly an amazing feat. Not surprisingly some infants may be slow to progress through this process. It is often an issue in infants that have little exposure to catecholamines due to a rapid operative delivery. Although these infants may require oxygen or CPAP, it is seldom that they need invasive ventilation.

MECONIUM ASPIRATION SYNDROME[18]

Meconium is the faecal material of an infant prior to and in the first days of life. Passage of meconium is normal after birth. Passage of meconium prior to or during birth is an indicator of fetal stress. If inhaled or aspirated by the infant during delivery it induces a chemical pneumonitis and obstructive lung disease. If there is meconium present and if the neonate is apnoeic, it is recommended that he/she is suctioned below the vocal cords before bag mask ventilation. Either intubation and suction via the endotracheal tube (ETT) or the use of a specialised meconium aspirator is recommended.

Once an infant develops meconium aspiration syndrome (MAS) the infant will need some degree of respiratory support. Non-invasive respiratory support and invasive ventilation are standard treatment options. Antibiotics are commonly administered as there is concern that sepsis might be an additional cause of fetal distress. Surfactant is deactivated by meconium and so surfactant therapy is used in severe cases. Surfactant lavage may also be employed as a rescue measure to facilitate the 'wash-out' of the lungs and replace surfactant deficiency. ECLS (extracorporeal life support) is indicated for severe MAS. Of all disease entities treated with ECLS (including all neonatal, paediatric and adult causes) it has the greatest survival. ELSO database figures show that survival from severe respiratory

failure due to MAS is upward of 90% with some units boasting near-100% survival.

NEONATAL PNEUMONIA[19]

Neonates are at constant risk from pneumonia. Due to the relative immaturity of their immune system they are particularly sensitive to encapsulated bacteria and to Gram-negative bacteria such as *Escherichia coli*, *Klebsiella* and *Serratia*. Group B *Streptococcus* is carried as a vaginal commensal by up to 50% of women so is a common neonatal pathogen. These organisms also cause sepsis and meningitis in infants and newborns. Early infections <14 days are likely to have come from the mother at birth, either prior to birth (chorioamnionitis, prolonged rupture of membranes) or by transplacental infection (*Listeria monocytogenies*).

Viruses such as cytomegalovirus, varicella and other herpesviruses tend to cause a generalised viraemia rather than an isolated pneumonia. Fungal and protozoan infections are virtually unheard of in causing a neonatal pneumonia and tend to cause a systemic infection.

PULMONARY HAEMORRHAGE[14]

Prematurity, surfactant deficiency and persistent fetal circulation with pulmonary hypertension all predispose an infant to risk of pulmonary haemorrhage. Vitamin K deficiency can also present with pulmonary haemorrhage, but gastrointestinal bleeding and intracerebral bleeding are far more common. Children with abnormal pulmonary vascularity of the bronchial arteries can present with catastrophic pulmonary haemorrhage; however, this tends to present later in life. Disseminated intravascular coagulation can result in pulmonary haemorrhage in the setting of severe sepsis.

DIAPHRAGMATIC PALSY[14]

Palsy of the diaphragm is almost exclusively a complication of cardiothoracic surgery. These infants are difficult to wean from ventilation. If there is paradoxical upward movement of the affected diaphragm during inspiration, surgery to plicate the diaphragm is required. This stabilises the affected hemidiaphragm so that the normal hemidiaphragm can still create a negative pleural pressure for inspiration. The palsy will often improve with time.

COMMON ACQUIRED DISEASES BEYOND THE NEONATAL PERIOD

BRONCHIOLITIS[20–24]

Bronchiolitis is the commonest cause of respiratory failure beyond the neonatal period in children. Bronchiolitis is caused by infection and inflammation in the bronchioles resulting in obstructive lung disease leading to hypoxia, tachypnoea and air trapping. CXR shows hyperinflation (and collapse) of lung segments and often right upper lobe collapse and /or consolidation. Respiratory syncytial virus (RSV), human metapneumovirus (hMPV), human bocavirus, adenovirus, parainfluenzae, influenza virus and rhinovirus are all implicated in the hospitalisation of children. Data from the Australasian ANZPIC registry shows that in 2011 RSV virus continues to make up the majority of acute viral bronchiolitis – 60% of children admitted to an ICU had RSV identified.

Treatment is largely supportive. The majority of infants can be supported with non-invasive respiratory support. About 65% of the children (mentioned above) were supported with non-invasive ventilation (NIV) techniques and high-flow nasal cannula oxygen (HFNC). Similar proportions are seen in the non-RSV bronchiolitis group. Only a few infants require invasive ventilation. These tend to be the very young infants in whom apnoea is a feature of the disease and infants with underlying medical conditions such as chronic lung disease, cardiovascular disease and neuromuscular disease.

Up to 20% of infants who require invasive ventilation for bronchiolitis have a concurrent bacterial infection so antibiotics are often started empirically until haematology and inflammatory markers become reassuring and cultures are negative. A number of infants with bronchiolitis who need respiratory support must be transferred from their regional hospital to the nearest PICU. Although transfer with non-invasive support can be done safely for short road transfers, aeromedical transfer often necessitates intubation to secure the airway for the limitations of the aeromedical environment.

Steroids, epinephrine (adrenaline), bronchodilators and hypertonic saline have been investigated for the treatment of bronchiolitis. None has consistently shown significant benefit in hospitalised children. Specific antiviral therapy is not indicated in the immunocompetent. Recombinant RSV antibody provides passive prophylaxis against RSV and is indicated in infants with chronic lung disease or congenital heart disease.

Bronchiolitis by definition is limited to the under-12-months age group. A number of other definitions apply to children of older ages such as viral pneumonia, reactive airways disease (if there is bronchodilator responsiveness) or wheezy bronchitis. These definitions change every few years reflecting the poor understanding we have of this very common disease.

PNEUMONIA[5,25]

ANZPIC data show about 16% of respiratory admissions were for pneumonia. About half of these patients required invasive ventilation. Community-acquired pneumonia is caused predominantly by viruses followed by staphylococcal and streptococcal bacteria.

Atypicals such as *Mycoplasma pneumoniae* and *Chlamydia* also feature. Respiratory support is escalated as required to support the work of breathing and provide acceptable gas exchange. Tidal volumes kept at between 5 and 8 mL/kg and permissive hypercarbia and hypoxia are the usual goals. Treatment with empirical antimicrobials based on local sensitivity patterns should commence as soon as possible. Antibiotics should be changed to narrow-spectrum agents once organism sensitivities are known. The exception to this rule is in the treatment of cystic fibrosis where broad-spectrum cover may be needed to mitigate against the development of antimicrobial resistance. Bronchoscopy for samples is often not possible owing to the small calibre of the endotracheal tube. Blind bronchoalveolar lavage is almost routine for intubated patients. Endotracheal suction samples are also used; however, poor sensitivity and specificity limit their value.

ASTHMA[26–28]

Asthma is frequently diagnosed in childhood but not all wheezy exacerbations are asthma. They may be manifestations of an acute viral illness that presents with a constellation of symptoms including wheezing and tachypnoea but do not respond to bronchodilators. As an intensive care physician it is important to make an assessment of these patients as to the underlying aetiology. The management of a wheezy lower respiratory infection is purely supportive but may often require some mechanical respiratory support.

Acute severe asthma requires specific treatments for the inflammation and bronchoconstriction that are the pathophysiological basis of asthma. For all but the most severe, metered dose inhalers and spacers have been shown to have superior drug deposition. If there is significant hypoxia, oxygen-driven nebulisers are necessary. Nebulisers of salbutamol and ipratropium bromide should be given as a matter of urgency. Salbutamol nebulisers may need to be given continuously. Once the oxygen and nebulised bronchodilators have commenced then steroids are the next most important part of the asthma management. Gastric stasis is common in acute severe asthma so oral steroids should not be relied upon. Anti-inflammatory doses of intravenous steroid should be given urgently to all patients who do not significantly improve with the initial burst of bronchodilators. Frequently, patients are also mildly dehydrated due to poor oral intake and increased insensible losses so a small fluid bolus can be helpful along with commencement of maintenance intravenous fluids.

Intravenous salbutamol is sometimes necessary but can lead to side-effects of tachycardia, tremor, lactic acidosis and resultant compensatory increase in respiratory drive. An intravenous bolus of magnesium sulphate and/or aminophylline will often improve bronchoconstriction in severe refractory asthma but can have adverse effects. These last three medications are contentious and have protagonists and antagonists. However, the side-effects of medical therapy are less than the risks of invasive ventilation.

NIV with CPAP or BiPAP is increasingly used in asthma. Asthma was thought to be a contraindication but NIV is now thought to have a place in acute severe asthma. It should not replace invasive ventilation if this is deemed to be necessary. Invasive ventilation should be approached with caution and with preparations made for managing cardiac arrest and pneumothorax should these occur. The approach taken for the ventilation of severe paediatric asthma is the same as for an adult patient. The reader is referred to Chapter 35 on asthma for the salient issues regarding ventilation of patients with asthma. Volume ventilation is preferred as this will adapt to the changing compliance of the lungs as the bronchi relax. High pressures may be needed. The alveoli are protected from these pressures by the airway obstruction. The combination of steroid therapy and muscle relaxants puts the child at risk for critical illness neuropathy/myopathy. Fortunately most children do not require more than 48 hours of ventilation. General anaesthesia and ECLS have been used on rare occasions.

Acute asphyxial asthma can present as a community cardiorespiratory arrest in children. The profound bronchoconstriction may have resolved by the time the child presents in the emergency department. These children have usually suffered a severe hypoxic ischaemic brain injury. It is exceptionally rare for a child who presents with severe asthma to have a respiratory arrest once therapy has begun but aggressive up-front therapy is mandatory.

Twelve per cent of respiratory admissions to Australasian PICUs in 2011 were for asthma and approximately 70% required no supportive ventilation; 10% were ventilated and the remaining 20% were treated with high-flow nasal cannula oxygen or NIV.

CROUP[5]

Croup or laryngotracheobronchitis is infection and inflammation of the upper and lower airways. Children are more prone to croup owing to the smaller airway radius. Further narrowing leads to marked increase in resistance (Poiseuille's law) and turbulent flow. In the past intubation was frequently required. Use of steroids and epinephrine (adrenaline) nebulisers now means very few children require intubation. If required, intubation for severe croup is best done in the operating theatre with a gaseous induction and preservation of spontaneous breathing. If there is no significant lower airway or lung parenchymal inflammation these children are often able to be supported with a nasal endotracheal tube and awake, sometimes ambulant. Parainfluenza virus is the commonest cause of this condition. Important differentials to consider with severe

stridor are: foreign body, bacterial tracheitis and epiglottis. Epiglottitis has become very uncommon with effective *Haemophilus influenzae* B vaccination.

TUMOURS

Neuroblastoma and lymphomas are the commonest tumours that develop in children and cause respiratory compromise. Lymphomas tend to arise centrally from mediastinal nodes. A rapidly growing mediastinal T-cell lymphoma is a true oncological emergency. Mediastinal compression results in life-threatening respiratory and cardiovascular compromise. Maintenance of spontaneous breathing and positioning the patient in a forward-sitting position are simple measures that may improve ventilation. Children will often find their own preferred position. Intravenous steroids may need to be commenced prior to diagnosis if the respiratory compromise is severe. Intubation of these patients is risky and best done in theatre with a gas induction and ENT surgeons on standby.

ACUTE NEUROMUSCULAR DISEASE

For the most part, the acute neuromuscular conditions that children succumb to are similar to those for adults. The reader is referred to the relevant chapters. Guillain–Barré, tetanus, botulism, acute demyelinating encephalomyelitis and acute spinal injury are supported and treated with supportive ventilation whilst expectantly awaiting return of neurological function. In Australia, tick bite paralysis can cause a severe paralysis in children. The toxin binds covalently with the acetylcholine receptor complex. The cholinergic block lasts long after the source of the toxin is removed. Not uncommonly, children require prolonged courses of supportive ventilation and intensive care. This is in contrast to the North American tick.

CHRONIC NEUROMUSCULAR CONDITIONS

Chronic neuromuscular disorders that are not diagnosed at birth are often diagnosed in infancy and early childhood. These children often require intermittent respiratory support with intercurrent illnesses. Many of these diseases are life-limiting and eventually children with severe neuromuscular or progressive conditions will suffer severe respiratory infections that need ventilation for prolonged periods. Cerebral palsy, Duchenne muscular dystrophy and spinomuscular atrophy are examples. Intubation can be difficult owing to scoliosis, limited jaw opening or facial dysmorphism. Ventilation is often troublesome due to chest wall deformity and underlying chronic lung disease. Weaning from ventilation is slow and laborious and may involve a protracted stay in the PICU on invasive ventilation and NIV. Some children cannot be weaned from invasive ventilator support after a severe infection so there is an increasing risk for these children that they will die a very medicalised death. End-of-life care and limitation of interventions are important issues to discuss with parents and care givers. Ideally these issues should be discussed prior to an acute illness so that parents and the child, if old enough, have time to consider the options without the stress of an imminent deterioration. Hopefully, some agreement can be reached and potential conflict between parents and PICU staff minimised at the time when the child is most unwell.

TRAUMA

The reader is referred to the chapters on head, chest and paediatric trauma. Pulmonary contusions and rib fractures are less common in small children. Head injury is common. As children grow, their bones ossify and they become involved in more risky activities so pulmonary contusions and rib fractures become more common. Infants tend to cope better with rib fractures, but older children have issues with pain and lung expansion, as experienced by adult patients.

Management of severe chest trauma in children is not different to that in adults: maintain distension of as much of the lung as possible, ensuring adequate ventilation with conventional or high-frequency oscillation and drainage of pneumothorax and haemothorax. Bronchoscopy can be useful for pulmonary toilet and removal of blood casts from the bronchial tree. Lung isolation and independent ventilation are difficult in children and seldom necessary.

ACUTE RESPIRATORY DISTRESS SYNDROME[3,4,29–31]

Acute respiratory distress syndrome (ARDS) may occur in children of all ages from a variety of direct and indirect lung insults, as it does in adults. In children, common causes of ARDS include shock, pneumonia, sepsis, near-drowning, aspiration and pulmonary contusion. ARDS is characterised by respiratory distress or failure, diffuse pulmonary infiltrates, reduced pulmonary compliance and hypoxia in the presence of a known precipitating cause and in the absence of left ventricular failure. ARDS is diagnosed when the ratio of the partial pressure of oxygen in arterial blood (Pa_{O_2}) to the fraction of inspired oxygen (Fi_{O_2}) is less than 200. This is the P/F ratio. Acute lung injury is diagnosed when the P/F ratio is less than 300. The P/F ratio in a healthy individual is approximately 500. Clinically P/F ratios are of little use. They define a degree of impaired gas exchange that makes some homogeneity of a heterogeneous situation, primarily for research purposes. Neonatal respiratory distress syndrome refers to respiratory distress that occurs in prematurely born infants as a result of inadequate surfactant production by their immature lungs. Treatment modalities for paediatric ARDS are very similar

to those for adults with the open-lung/low-tidal-volume strategy, and acceptance of permissive hypoxia and hypercarbia. High-frequency oscillatory ventilation is commonly employed and ECLS is considered if there is a reversible or treatable cause. The reader is referred to Chapter 33 on ARDS.

FOREIGN BODIES

Laryngeal, tracheal and bronchial foreign bodies are commonplace in children. Most commonly foreign bodies that enter the airway (as opposed to oesophagus) become lodged, if they traverse the cords, at the level of the cricoid membrane (the narrowest part of the paediatric airway). The shape of the foreign body is of crucial importance as to its final resting place. Sharp and slender foreign bodies (such as needles) and particulate food material (i.e. pieces of nuts) travel further down the bronchial tree. Nut fragments and food particles are an important cause of morbidity. In particular, peanuts release arachidonic acid, which causes local inflammation. The resultant inflammation causes stenosis of the airway and pneumonia beyond the level of the obstruction. Bronchoscopy (flexible and rigid) should be performed if there is any concern of a foreign body.

IMMUNOCOMPROMISED PATIENTS[29,32]

A PICU within a hospital with an active oncology service and importantly a bone marrow transplant service will see a significant number of immunocompromised children. Not uncommonly, they present with generalised sepsis, localised pulmonary sepsis, or with pulmonary complications of conditioning regimens for transplant. Similarly if there is a solid organ transplant service (heart, liver, kidneys, lungs and small bowel) they all require degrees of systemic immunosuppression.

The amount of HIV that is seen in a paediatrics unit mirrors that seen in the heterosexual community as the majority is from maternal transmission. Developing and Third-World countries where HIV rates are extremely high in the adult population will see a lot more HIV in their critically unwell patients.

Undiagnosed leukaemia and lymphomas can present with respiratory failure due to: immunosuppression and sepsis, extremely high peripheral white cell counts causing sludging in the pulmonary circulation, or local compression of respiratory structures (see above). Some malignancies present with respiratory sequelae of disseminated intravascular coagulation (acute myeloid leukaemia) or with multisystem failure (haemophagocytic lymphohistiocytosis).

Genetic immunodeficiency states are rare. Severe combined immunodeficiency (SCID), combined variable immunodeficiency (CVID) and chronic granulomatous disease can all present with severe respiratory failure in undiagnosed patients. T-cell defects present with opportunistic infections such as *Pneumocystis*, *Nocardia* and fungal infections. B-cell deficiencies generally present with severe viral or encapsulated bacterial infection. Chronic granulomatous disease presents with recurrent bacterial infections that need an effective oxidative burst to destroy them (e.g. *Staphylococcus aureus*). Infection with an unexpected organism or severe respiratory failure in an infant that cannot be explained warrants a thorough investigation and assessment of the patient's immunocompetence.

Treatment of respiratory failure in the immunocompromised is directed toward the primary problem along with the respiratory support and antimicrobial therapy as appropriate. In some cases the immunosuppression, with steroids for example, may need to be decreased. In many chemotherapy and bone marrow transplant regimens, bone marrow stimulation or autologous stem cell rescue is used to minimise the period of neutropenia and minimise the risk of sepsis in the face of aggressive chemotherapy.

INVESTIGATIONS

RADIOLOGY[33,34]

Although chest X-ray is often mandatory in patients with respiratory disease to delineate the extent of lung involvement, the presence of pneumothorax or effusion or to check the position of the ETT and central venous lines, routine radiology investigations can expose children to unnecessary ionising radiation. Investigations that use ionising radiation should be done only if they will answer questions important to diagnosis or management of the patient. Exposure to medical radiation as a percentage of total lifetime radiation has been estimated to have risen from 15% to 50% in the USA over the last 30 years: CXRs are a significant contributor to this radiation. Children are most at risk. A chest computed tomography scan (CT) has a 1:1000 chance of inducing malignancy. Lateral CXR in children only rarely provides additional information over the anterio-posterior view so is a waste of medical radiation if used routinely.

Standard CT and high-resolution spiral CT with thin cuts can provide better diagnostic detail than a plain CXR; however, their use should be justified in light of the increasing lifelong radiation exposure and the risk of transporting a critically ill patient to the scanner.

Magnetic resonance imaging (MRI), though not a good modality for the lung parenchyma, does not use ionising radiation and is safe with cumulative dosing.

Ultrasound is becoming routine in emergency departments and ICUs. Focused chest ultrasound can assist in the diagnosis of pneumonia, pleural effusions and pneumothorax with only a small amount of training. Ultrasound should be used routinely for the placement of central venous lines and is able to assist with

the insertion of chest drains, placement of intra-arterial lines and peripheral intravenous lines (where veins are not visible on the skin surface).

MICROBIOLOGY[19,22,24,35,36]

Appropriate microbiological samples have a crucial role in diagnosis and therapy. It is important to sample blood and respiratory secretions prior to administering antimicrobial therapy if possible.

Nasopharyngeal aspirate or nasal brushings for immunofluoresence and viral DNA/RNA polymerase chain reaction (PCR) can detect a significant number of viral infections of the respiratory system. RSV and hMPV are by far the most common.

Bronchoscopy is used in the PICU but to a lesser extent than in the adult ICU. It is used to inspect the airways, clear secretions and obtain samples. The need to use very small bronchoscopes for infants, limited experience and reduced availability of equipment limit the utility of this modality in the PICU. When required it is undertaken by respiratory physicians or intensivists with a keen interest.

THERAPY FOR CHILDREN WITH SEVERE RESPIRATORY FAILURE

SUPPORTIVE CARE/FAMILY-CENTRED CARE

Even in the most critically ill children, parents are encouraged to be involved with the care of the child as much as is practical. The calming influence of a parent or grandparent cannot be understated, and is an important adjunct to sedation regimens in PICU and NICU. By inviting parents to participate in the care of their critically ill child, a partnership is forged that promotes trust and compliance with necessary medical interventions. In the event that the child does not survive, the benefit for the parents in the subsequent grieving process should not be underestimated. Siblings may also benefit. Occasionally, the sickest children are very sensitive to stimuli so deep sedation, muscle relaxation and minimal handling are required.

NORMOTHERMIA, FLUID BALANCE AND NUTRITION[37]

Maintenance and promotion of homeostasis is the hallmark of good intensive care. This includes adequate nutrition, euvolaemic fluid balance and normothermia (unless therapeutic hypothermia is undertaken). Small infants have a large body surface to weight ratio so maintenance of normothermia can be challenging, particularly during procedures and transportation around and between hospitals. Clinicians and nursing staff need to pay particular attention at these times. Adequate nutrition promotes recovery from critical illness so nutritional goals should be set early in the course and all attempts made to reach these goals, including the use of transpyloric feeding tubes and intravenous nutrition if required. Usually it is a struggle to achieve required goals but avoidance of overfeeding is also important. Impaired carbon dioxide clearance in severe respiratory failure makes this vital. Minimisation of fluid overload and increased lung water are crucial and can lead to prolonged ventilator weaning if not addressed. Diuretics are commonly used to treat generalised oedema but have side-effects of electrolyte imbalance and metabolic alkalosis. If fluid overload can be avoided then this is recommended.

ANTIMICROBIAL USE

Antimicrobial use should always be with consideration of the local pattern of pathogen sensitivities and promote good antimicrobial stewardship to minimise the impact of resistance patterns. Patients on antimicrobial therapy often benefit from specific input by infectious diseases specialists and routine consultation is an important part of antimicrobial stewardship.

GOOD HOUSE-KEEPING/ NOSOCOMIAL ISSUES

Children suffer complications of critical-illness-related therapies and immobilisation. Ventilator-associated pneumonias and other nosocomial infections can complicate the PICU course. Patients are at risk for dependent skin pressure areas and at contact points with medical devices. Thromboprophylaxis is important but it is less clear exactly who to treat. Protocolised care and the use of ‘bundles’ help to minimise the impact of these hospital-related morbidities. Local quality audit, assessment and focusing on improving areas peculiar to the specific unit are important. Good ‘house keeping’ in NICU and PICU is as important as the treatment of the underlying condition causing respiratory failure.

NON-INVASIVE RESPIRATORY SUPPORT

HIGH-FLOW NASAL CANNULA (HFNC) OXYGEN THERAPY[38–45]

HFNC oxygen therapy has made its way rapidly into the PICU armament of support. Its introduction has preceded the supportive research relating to its use. None the less, it appears to be a very useful tool at the lower end of respiratory support. HFNC oxygen therapy consists of a simple circuit comprising of a gas flow regulator, an oxygen mixer, a humidifier, a gas warmer, large-calibre tubing and a patient interface. The patient interface is most commonly a soft plastic or silicone nasal cannula. The cannula may be semiocclusive of the nares or non-occlusive. The idea is that gas inspired by the patient is preferentially derived by the flow through the circuit. Hence the flow must be at least the instantaneous peak inspiratory flow of the patient to avoid entrainment of environmental gas. HFNC is

also thought to provide a small amount of positive airway pressure. This therapy is used increasingly in NICUs and PICUs for patients who need mild respiratory support. HFNC is safe, cheap and provides the support that a number of patients need beyond standard low-flow oxygen therapy.

Data from the ANZPIC registry 2011 reveal the impact HFNC therapy is having. HFNC accounts for almost 20% of the sole support given to patients with a respiratory diagnosis. Approximately 24% were supported with invasive ventilation and 35% with NIV. The remainder of patients were managed with a combination of the three therapies.

NASAL AND FACE MASK NON-INVASIVE VENTILATION[32,46–48]

The benefit that neonates derive from NIV is matched by the number of different systems to provide this type of support. Supporting premature neonates in this way is effective and beneficial and avoids many risks associated with long-term invasive ventilation. Even very premature infants can have a brief period of invasive ventilation, surfactant instillation and then the majority of their time they are supported on bubble CPAP for the weeks and months they are in the NICU. Neonatologists as a rule use a nasal prong patient interface. This is due to its simplicity, lack of bulk, ease of securing and effectiveness. As patients grow the use of masks becomes easier and the NIV devices are more able to synchronise and provide BiPAP effectively. Soft malleable facial structure, general uncooperativeness of patients and difficulties with adequate seal make patient interfaces difficult to match with individual patients. Newer plastics, manufacturing of devices and improved cushioning help to decrease these problems. Older children, like adults are most suited to mask ventilation support. However, with persistence and a range of masks younger children can be supported with NIV.

Triggering and delivery of support can be limited in some devices. Despite the advertising and salesmanship of ventilator companies, very few devices are suitable for small children. This is likely to change in the future.

The single most important resource, other than equipment, is experienced personnel who are able to persevere, use alternative interfaces and understand the equipment. In the acute setting it is very common to require sedation to augment patient compliance with the NIV. This should be used only where suitable staff members are present and emergency equipment is available for intubation.

INVASIVE VENTILATION[6,7,25,48]

CUFFED VERSUS UNCUFFED ETT/NASAL VERSUS ORAL[49,50]

The debate regarding cuffed versus uncuffed ETT is not likely to be resolved. Both types are reasonable to use and each type has its advantages and disadvantages. For short-term use, security and reliable ventilation most paediatric anaesthetists would prefer a cuffed ETT. In PICU when ventilation is expected to be difficult or when changing the ETT is likely to cause significant deterioration, cuffed ETTs are preferred. For longer-term PICU management the issue is less clear. Cuffed ETTs need to be the appropriate size and care taken to monitor inflation pressure and positioning of the cuff. With either cuffed or uncuffed ETT, a leak of inspired gas around the ETT (cuff deflated if present) is a desirable finding when considering extubation and risk of post-extubation stridor. Presence of a leak does not guarantee the patient will not suffer this complication. Usually it is local policy that directs the use of one or the other.

Nasal verses oral positioning for long-term ETTs is another contentious issue. Either route is used up to the age of around 8 years when maxillary and ethmoid sinuses become aerated. Oral intubation is used first when intubating a critically unwell child due to lack of reserve and the need to expedite positive-pressure ventilation. If the intubation is uncomplicated and the patient tolerates the procedure then the ETT may be changed to a nasal ETT. However, this is dependent on local PICU policy and preference rather than clear evidence. Arguably, a nasal ETT is more comfortable for the patient and easier to secure but can cause pressure areas. The risk of changing the ETT should override any decision to match the culture of the PICU with respect to positioning of the ETT.

CONVENTIONAL VENTILATION[51,52]

The debate as to volume- or pressure-regulated ventilation is ongoing although it appears that volume control may be more lung protective. Pressure control ventilation has historically been used in children owing to early ventilators not being able to guarantee delivery of the small tidal volumes that babies and infants require. With newer, more sophisticated ventilators the volume control can be adjusted up the nearest millilitre. Accurate volume measurement also requires the use of cuffed ETT in a majority of cases.

Triggered modes are used in patients who are spontaneously breathing. The aim is to have the patient lightly sedated, exercising the respiratory muscles and synchronising well with the ventilator. Appropriate triggering, inspiratory time and cycling to expiration are all important to synchrony.

Positive end-expiratory pressure (PEEP) of at least 5 cmH_2O (0.66 kPa) is routinely used in all paediatric and neonatal patients, albeit empirically. Children expire to near their functional residual capacity so that any loss of muscle tone will lead to greater likelihood of pulmonary atelectasis – hence a small amount of distending pressure is desirable. As in adults, PEEP is increased and recruitment manoeuvres are used to promote open lung ventilation. PEEP is unlikely to be increased beyond 15 cmH_2O (2 kPa). Adult strategies advocate higher PEEP but neonatal and paediatric preference is usually to change to high-frequency

oscillator ventilation (HFOV) if adequate gas exchange cannot be maintained.

HIGH-FREQUENCY OSCILLATOR VENTILATION[30,53,54]

HFOV has been instrumental in the care of infants with severe respiratory failure from any number of causes. In essence it is a set pressure – the mean airway pressure (MAP), with oscillation of 6–12 Hertz around this. Oscillations are sinusoidal with negative and positive deflections. MAP, frequency and amplitude of the ventilator waveform influence oxygen and carbon dioxide clearance in discrete but not entirely independent ways. MAP and inspired oxygen are the primary determinants of oxygenation. Frequency and amplitude are the primary determinants of carbon dioxide clearance. Alveolar ventilation is said to occur by convective and diffusional mechanisms. These include bulk gas movement, laminar and turbulent flow, Pendeluft ventilation (between alveoli), collateral ventilation by alveolar channels and Taylor dispersion.

Children ventilated with HFOV are often heavily sedated and have neuromuscular-blocking agents administered. However, depending on pathology and stability, they may be allowed to breath on top of the oscillations of the ventilator. These spontaneous breaths are not supported so the clinician must ensure that the bias flow through the circuit is sufficient to maintain the MAP and allow for this tidal ventilation by the patient. For neonates and small infants this tidal volume is negligible compared with the bias flow. For older children this can be challenging and unachievable. Secretion clearance and humidification of gases can be challenging. High bias flow results in inadequate humidification while rain-out within circuits is frequently an issue. Weaning can be achieved while on HFOV, but most units convert to conventional ventilation for weaning, especially in older children who need larger tidal volumes.

VENTILATOR STRATEGIES[6,30,54]

Many ventilation concepts such as permissive hypercarbia, permissive hypoxia and open-lung ventilation came from the NICU and the management of respiratory distress syndrome in premature infants and the management of pulmonary hypoplasia in CDH. The single-organ disease and the desire of clinicians to improve outcomes and minimise morbidity drove the development in this area and credit must be given to the large number of clinicians and researchers who advanced this area.

ARDSNET has taken these concepts and demonstrated they can be translated to adult practice. Further studies followed. Although there are many criticisms of the studies they have taught us a lot about ventilation and iatrogenic morbidity that is potentially avoidable.

The best ventilation strategy gives a reasonable amount of gas exchange to meet metabolic tissue demands whilst minimising trauma (barotrauma, volutrauma, sheer stress, bio-trauma, etc.) on the lungs. Debate will rage for generations as to the best way to ventilate a critically unwell patient.

ICUs are dangerous places for patients. The modality keeping most patients in ICU is mechanical ventilation. Ventilation is hazardous and it is important to liberate the patient from dependence on mechanical support of any type as expeditiously as possible. Physicians, nurses and allied health staff must be proactive and creative to achieve this.

EXTRACORPOREAL LIFE SUPPORT (ECLS)[18,55,56]

Historically, adult ICUs had abandoned ECLS in the face of poorly constructed studies while NICUs and PICUs fostered and nurtured its development. Dramatic improvements in ECLS were promoted by improvements in cardiopulmonary bypass technology, developments in congenital heart surgery and the need to support neonates with severe respiratory failure such as meconium aspiration. Neonates across the spectrum of the ELSO registry have the greatest survival rates.

ECLS for neonates, infants and small children is typically achieved by surgical cannulation in the neck with the right common carotid and right internal jugular vein being accessed. Femoral vessels may also be used in older children but are unable to provide adequate flows in babies and infants. Veno-arterial ECLS is common, but veno-venous ECLS via a double-lumen catheter or two-vein cannulation is becoming more common for pure respiratory support.

Paediatric fluid and electrolyte therapy

Frank Shann

Children need a much higher intake of water and electrolytes per kilogram of body weight than adults; this makes children more susceptible to dehydration if they have abnormal losses of water or a reduced intake. On the other hand, an inability to excrete a water load, due to immature kidneys (in neonates) or high levels of antidiuretic hormone (ADH), means that children can easily be given too much water intravenously. There are good reviews of fluid and electrolyte therapy in paediatric and neonatal intensive care[1–5] (see **Box 106.1**).

WATER

The full-term neonate is 80% water; this figure falls to about 60% by 12 months of age, and then remains almost constant throughout childhood. The intravenous (i.v.) fluid requirements for children in hospital are shown in **Tables 106.1** and **106.2**. The widely used formula for an active child shown in Table 106.2 was published in 1957,[6] and some of the measurements of energy expenditure were made almost a hundred years ago. The formula is a compromise between the requirements of a fully active child and the much lower requirements at basal metabolic rate – for example, the estimate of 100 mL/kg/day for an active 10-kg child in hospital is double the 50 mL/kg/day needed for a sick child at basal state (Table 106.2).[6,7]

Table 106.3 shows that very ill children in intensive care often need much less water than the 'standard' amounts that are often given.[1,6,8–13] For example, if a 15-kg child ('standard' maintenance fluid of 50 mL/h,[6] Table 106.1) sustains a head injury and has evidence of high levels of ADH (maintenance fluid×0.7),[9] is ventilated with humidified gas (maintenance×0.75),[8] is paralysed (basal state, maintenance×0.7),[6] and is maintained at a rectal temperature of 36°C (maintenance−12%),[1] then his actual full maintenance fluid requirement is (50×0.7×0.75×0.7) − 12%=16 mL/h. Even less water should be given initially if the child is overhydrated.

In very small children, all fluid administered has to be taken into account – including the volume of drugs (bicarbonate, dextrose and antibiotics) and 'flushes' used to clear i.v. lines (after blood sampling or administration of drugs).

The estimates of water requirements in Tables 106.1–3 are only approximate, and water balance must be monitored closely in any child in intensive care. Unfortunately, regular, accurate weighing of very sick children is often impractical, and hydration has to be assessed using the serum sodium concentration, skin turgor, urine output (minimum 0.5–1.0 mL/kg/h) and central venous pressure.

In a child with oliguria following a severe ischaemic or hypoxic insult (such as birth asphyxia, drowning or cardiac arrest), it may be helpful to measure the urine sodium concentration.[14] In oliguria due to acute tubular necrosis, where restriction of fluid intake may be necessary, the urine sodium is usually more than 40 mmol/L. In oliguria due to hypovolaemia, the urine sodium is usually less than 20 mmol/L.

SODIUM

Sodium is predominantly an extracellular ion, so total body sodium is well represented by the serum concentration; it must be interpreted in the context of both total hydration and the relative amounts of water and sodium. Acute changes in serum sodium are usually due to changes in body water rather than changes in body sodium.

In the first 1 or 2 days of life, small preterm babies often have poor urine output and high transcutaneous fluid losses. They are therefore prone to hypernatraemia and hyperkalaemia, and such infants should usually be given 5% or 10% dextrose without sodium or potassium. From 2 days of age, 2–4 mmol/kg/day of sodium and potassium will usually be sufficient, but much higher intakes of sodium are needed in some preterm neonates owing to their impaired renal conservation of sodium.

Hyponatraemia may be due to:[16]

- increased body water due to excessive water intake, especially in the presence of high levels of ADH (CNS disease, intermittent positive-pressure ventilation (IPPV), lung disease, vomiting, stress)
- low body sodium due to diuretic therapy, poor renal conservation of sodium, or a low sodium intake (e.g. breast milk).

Acute hyponatraemia causes cerebral oedema, with a grave risk of cerebral herniation and death or severe brain damage.[17] Hyponatraemia due to sodium deficit

Table 106.1 Approximate intravenous fluid requirements for children (mL per hour)

	WEIGHT IN KG											
	3	5	7	10	15	20	25	30	40	50	60	70
Active	12	20	30	40	50	60	65	70	80	90	95	100
Sick	6	10	14	20	25	30	35	40	45	55	60	70
Intubated	4	7	10	14	17	21	25	28	32	40	45	50

Box 106.1 Key points

- Children in intensive care usually need much less water than the 'standard' maintenance amounts (see Table 106.1)
- Hypovolaemia should be corrected with 10 mL/kg boluses of 0.9% saline
- Isotonic 0.9% saline should be used as the maintenance fluid in ill children, with careful monitoring of the serum sodium
- Hypoglycaemia is very dangerous in infants, and hyperglycaemia is less dangerous than in adults
- In hyponatraemia, the serum sodium should rise no faster than 8 mmol/L per 24 hours
- In hypernatraemia, the serum sodium should fall no faster than 0.5 mmol/L per hour
- Potassium should be given intravenously no faster than 0.3 mmol/kg per hour
- Oedema with low serum osmolality and high urine osmolality is often due to excess water administration to a child with high levels of antidiuretic hormone – the main treatment is fluid restriction
- Oedema caused by capillary leak will not respond to diuretic therapy or dialysis – large amounts of fluids may be needed to preserve the intravascular volume
- In adults resuscitated with 4% albumin rather than 0.9% saline, mortality tended to be lower in sepsis and higher in trauma, but the differences were not statistically significant – saline is much less expensive

should be corrected by careful administration of sodium (**Table 106.4**). However, hyponatraemia is usually due to water excess rather than sodium deficiency, and this should be treated with restriction of water intake; if symptomatic, it can be corrected by careful administration of 3% sodium at 0.5 mL/kg/h (Table 106.4), and furosemide 0.5 mg/kg intravenously if there are high ADH levels. Hyponatraemia must be corrected slowly: the serum sodium should increase by no more than 8 mmol/L each 24 hours, and even less in patients with long-standing hyponatraemia.[16]

Hypernatraemia may be due to:[15]

- reduced body water (dehydration) from a large insensible fluid loss (caused by radiant heaters or phototherapy), diarrhoea, osmotic diuresis (caused by glycosuria) or inadequate fluid intake

Table 106.2 Approximate intravenous fluid requirements for children (mL/kg/day)

ACTIVE CHILD IN HOSPITAL	
<10 kg	100 mL/kg/day
10–20 kg	1000 mL+(50 mL/kg/day for each kg over 10 kg)
>20 kg	1500 mL + (20 mL/kg/day for each kg over 20 kg)
SICK, BUT NOT INTUBATED	
<10 kg	50 mL/kg/day
10–20 kg	500 mL+(30 mL/kg/day for each kg over 10 kg)
>20 kg	800 mL+(20 mL/kg/day for each kg over 20 kg)
INTUBATED, WITH HUMIDIFIED INSPIRED GASES	
<10 kg	35 mL/kg/day
10–20 kg	350 mL+(20 mL/kg/day for each kg over 10 kg)
>20 kg	550 mL + (12.5 mL/kg/day for each kg over 20 kg)

Table 106.3 Modifications to the fluid intakes for active children shown in Table 106.2

	ADJUSTMENT
DECREASE	
Humidified inspired air[8]	×0.75
Basal state (e.g. paralysed)[6]	×0.7
High ADH (IPPV, brain injury)[9]	×0.7
Hypothermia[1]	12% per °C
High room humidity[1]	×0.7
Renal failure[1]	×0.3 (+urine output)
INCREASE	
Full activity + oral feeds[6]	×1.5
Fever[1]	+ 12% per °C
Room temperature >31°C[1]	+ 30% per °C
Hyperventilation[10]	×1.2
Neonate – preterm (1–1.5 kg)[11]	×1.2
– radiant heater[12]	×1.5
– phototherapy[13]	×1.25
Burns – first day[1]	+4% per 1% area burnt
– subsequently[1]	+2% per 1% area burnt

ADH=antidiuretic hormone; IPPV=intermittent positive-pressure ventilation.

Table 106.4 Doses and formulae in paediatric fluid and electrolyte therapy

Albumin 20%	Undiluted: 2–4 mL/kg
5%	5% in 5% dextrose or saline:
Bicarbonate (number of mmol of deficit):	Under 5 kg: base excess×wt (kg)×0.5 (give half of this) Over 5 kg: base excess×wt (kg)×0.3 (give half of this)
Blood volume	85 mL/kg in neonate 70 mL/kg in older child
Calcium	Chloride 10% (0.7 mmol/mL Ca^{2+}): maximum 0.2 mL/kg i.v. stat, requirement 1.5 mL/kg/day Gluconate 10% (0.22 mmol/mL Ca^{2+}): maximum 0.5 mL/kg i.v. stat, requirement 5 mL/kg/day
Dextrose	For hypoglycaemia: 1 mL/kg 50% dextrose i.v. in neonate: 4 mg/kg/min (2.4 mL/ kg/h 10% dextrose) day 1, increasing to 8 mg/kg/min (up to 12 mg/kg/min with hypoglycaemia) For hyperkalaemia: 0.1 u/kg insulin and 2 mL/kg 50% dextrose i.v. stat
Magnesium	Chloride 0.48 g/5 mL (1 mmol/mL Mg^{2+}): 0.4 mmol (0.4 mL)/kg/dose slow i.v. 12-hrly Sulphate 50% (2 mmol/mL Mg^{2+}): 0.4 mmol (0.2 mL)/kg/dose slow i.v. 12-hrly
Mannitol	0.25–0.5 g/kg/dose i.v. (1–2 mL/kg of 25%) 2-hrly, provided serum osmolality <330 mosm/kg
Packed cells	10 mL/kg raises Hb 3 g%; 1 mL/kg raises PVC 1%
Potassium	Maximum 0.3 mmol/kg/h, requirement 2–4 mmol/kg/day, 1 g KCl = 13.3 mmol K^+. Hyperkalaemia: see dextrose
Sodium	Depletion: 3% saline at 0.5 mL/kg/h (maximum Na rise 8 mmol/L in 24 h); requirement 2–6 mmol/kg/day, 1 g NaCl =17.1 mmol/Na^+
Urine	Minimum acceptable is 0.5–1.0 mL/kg/h

- increased body sodium from administration of large amounts of sodium (e.g. sodium bicarbonate) or salt poisoning.

With hypernatraemic dehydration, shock should be treated with boluses of 10 mL/kg of 0.9% saline. The water deficit should then be corrected very slowly using 0.9% saline so that the serum sodium falls no faster than 0.5 mmol/L/h, to prevent cerebral oedema.[15] If salt ingestion causes severe acute hypernatraemia without dehydration, peritoneal dialysis or haemofiltration may be indicated.

POTASSIUM

Potassium is predominantly an intracellular ion, so total body potassium is poorly represented by the serum concentration. The concentration of potassium in the serum depends on pH as well as the total body potassium (which is usually about 50 mmol/kg). A child may have hypokalaemia without a deficit of total body potassium in the presence of alkalosis and, conversely, there may be a large deficit of potassium without hypokalaemia in the presence of acidosis. Potassium should rarely be infused at more than 0.3 mmol/kg/h, and it should not normally be given to a patient with severe oliguria or anuria.

CALCIUM, MAGNESIUM AND PHOSPHATE

Hypocalcaemia in children occurs in:

- sick neonates in the first 2 days of life
- infants of diabetic mothers
- exchange transfusion with citrated blood (a temporary effect)
- magnesium deficiency
- infants fed cows' milk (which has a high phosphate content).

Hypocalcaemia and hypomagnesaemia cause jitters, tetany, cardiac arrhythmias and convulsions. The doses of calcium and magnesium are given in Table 106.4. The normal intravenous maintenance requirements in infants are 1 mmol/kg/day of calcium and 0.3 mmol/kg/day of magnesium.

STANDARD PAEDIATRIC MAINTENANCE FLUIDS

'Maintenance solution' is an unfortunate term, since these solutions do not provide maintenance calorie or protein requirements (see Parenteral nutrition, below). Until recently, it was common practice to give children a hypotonic maintenance solution of approximately 0.2% saline in 4% dextrose in generous amounts – based on the water requirements of an active child.[6] This policy resulted in a high incidence of hyponatraemia – and far too many children developed cerebral oedema that resulted in death or severe brain damage.[17,19–22]

Several factors have contributed to the high incidence of hyponatraemia in children. First, the amount of dehydration present is often overestimated,[23] and rapid administration of an excessive amount of fluid will cause hyponatraemia even if 0.9% saline is given – because the increase in intravascular volume will cause the production of urine containing more than 154 mmol/L of sodium (the amount present in 0.9% saline).[24] Secondly, the formula that is widely used to calculate maintenance water requirements is based on the needs of active children, and prescribes too much fluid for a sick child (Table 106.2).[17] Thirdly, many sick children have increased secretion of antidiuretic hormone even in the absence of hypovolaemia,[25,26] so they are unable to excrete the excess water when they are given large amounts of fluid. Fourthly, some sick children lose substantial amounts of sodium in their urine, perhaps due in part to the excretion of ketones as sodium salts.[22]

There is general agreement that an isotonic fluid such as 0.9% saline should be used to correct hypovolaemia, but there has been spirited debate about whether hypotonic 0.2% saline or isotonic 0.9% saline should be used for maintenance.[5,27,28] The supporters of using 0.2% saline argue that it is logical and safe provided the volume of fluid given is never in excess of actual requirements,[29–31] but there is limited empirical evidence to support this theory.[31] The supporters of using 0.9% saline for initial maintenance therapy in sick children (with careful monitoring of the serum sodium) argue that, in practice, this has been preferable,[17,19–22] because it is difficult to ensure that no excess fluid is administered, and there is a lower risk of hyponatraemia and cerebral oedema if any excess fluid that is given is isotonic. It is especially important to use isotonic fluid during and after surgery, and whenever there is a high risk of cerebral oedema (for example, amongst children with diabetic ketoacidosis or brain injury).[5,19–22,27,28]

Ill children with clear signs of hypovolaemia should be treated with 5–10 mL/kg boluses of 0.9% saline until the intravascular volume has been restored, and then given 0.9% saline (with potassium and dextrose as required) in the volumes shown in Tables 106.1 and 106.2 (or calculated from Table 106.3). The serum sodium concentration should be monitored carefully. If it is less than 138 mmol/L and falling, then less 0.9% saline should be infused. If the serum sodium is more than 142 mmol/L and rising, then 0.45% or 0.2% saline should be infused with a cautious increase in the rate.

Great care should be taken to avoid hypoglycaemia in children. Hypoglycaemia is particularly dangerous in young infants,[32] whereas hyperglycaemia is probably less dangerous in children than it is in adults in intensive care.[33]

The key messages are:

- correct hypovolaemia using 10 mL/kg boluses of 0.9% saline
- most sick children need far less maintenance fluid than previously thought (Table 106.1)
- use isotonic maintenance fluid for the first few days of treatment with careful monitoring of the serum sodium
- avoid hypoglycaemia.

DEHYDRATION AND SHOCK

Weight loss is the best guide to the degree of dehydration, if a recent weight is known. Many of the commonly used clinical signs of dehydration in children are inaccurate, and this leads to dehydration being diagnosed when it is not present, and to overestimation of the degree of dehydration.[23] The clinical signs of mild to moderate dehydration become apparent with only 3–4% dehydration in children.[23] The most reliable signs are:[34]

- decreased peripheral perfusion (as shown by pallor or reduced capillary return)
- deep breathing
- decreased skin turgor.

In children with shock, intravenous access may be difficult. In these circumstances, parenteral fluid can be given rapidly into the bone marrow, which is an intravascular compartment.[35] The usual sites chosen are the junction of the upper and middle third of the tibia (0–12 months of age), the medial malleolus (1–5 years) and the iliac crest (over 5 years). A 0.9 mm (20 gauge) lumbar puncture needle or an intraosseous needle can be used; the needle is held perpendicular to the bone and pushed in *gently* with a rotary motion about its long axis – a slight decrease in resistance will be felt as the needle enters the medulla. In infants with a patent anterior fontanelle, the superior sagittal sinus is an excellent way to gain intravenous access in an emergency.[36]

Shock should be treated with an initial bolus of 10 mL/kg of 0.9% saline, followed by further boluses of 10 mL/kg until the intravascular volume has been restored.[37] After shock has been corrected with a rapid infusion of fluid, the remainder of the deficit is

Table 106.5 Composition of some body fluids in children

FLUID	NA^+ (MMOL/L)	K^+ (MMOL/L)	CL^- (MMOL/L)	HCO_3^- (MMOL/L)	OTHER
Gastric fluid	20–80	10–20	100–150	0	H^+ 30–120
Bile	140–160	3–15	80–120	15–30	
Pancreatic fluid	120–160	5–15	75–135	10–45	Basal state
Jejunal fluid	130–150	5–10	100–130	10–20	
Ileal fluid	50–150	3–15	20–120	30–50	
Diarrhoeal fluid	10–90	10–80	10–110	20–70	
Sweat					
Normal	10–30	3–10	10–35	0	
Cystic fibrosis	50–130	5–25	50–110	0	
Burn exudate	140	5	110	20	Protein 30–50 g/l
Saliva	10–25	20–35	10–30	2–10	Unstimulated

replaced over the next 48–72 hours, while giving maintenance requirements using 0.9% saline with dextrose and potassium chloride. Thus, a 5-kg child with 10% dehydration from diarrhoea (500 mL deficit) might receive 100 mL (20 mL/kg) of isotonic saline rapidly to restore the circulation, leaving a 400 mL deficit to be replaced over 48 hours. If the maintenance requirement is 250 mL/day (Table 106.2), then the child should be given a further 450 mL of 0.9% saline per day for the next 2 days (approximately 20 mL/h) in addition to the initial 100 mL. Further abnormal fluid losses should be replaced with an appropriate fluid (see **Table 106.5**).

In a randomised study of 3141 East African children with severe febrile illness and signs of poor peripheral perfusion, children given 20–40 mL/kg boluses of 5% albumin or 0.9% saline had a significantly *higher* mortality at 48 hours and 4 weeks than children not given a fluid bolus.[38] However, only 2.1% of the children satisfied WHO's criteria for shock, and many of the 3141 children had severe anaemia, pneumonia, meningitis or encephalopathy and were at risk of overhydration.[39] The study therefore does not show that fluid boluses are dangerous in hypovolaemic shock.

With hypernatraemic dehydration, shock should be treated as above, with rapid infusion of 10–20 mL/kg of isotonic saline. The remaining deficit should then be replaced *slowly* with 0.9% saline so the serum sodium falls no faster than 0.5 mmol/L/h, to prevent cerebral oedema.[15]

In dehydration due to pyloric stenosis there is a deficit of water, hydrogen ion, chloride and potassium. Hypovolaemia should be treated by rapid infusion of 10–20 mL/kg of 0.9% saline, then 0.9% saline in 5% dextrose with 40 mmol/L of potassium chloride should be given at 50 mL/kg/day with careful monitoring of the serum electrolytes and blood glucose.

OEDEMA

Oedema is common in children in intensive care units. It may be due to:

- excess water intake, often with high levels of ADH (from CNS disease, IPPV, or lung disease)
- capillary leak (due to the effects of hypoxia, ischaemia, acidosis or sepsis)
- hypoalbuminaemia
- heart failure or renal failure.

Several possible causes are often present in one child, and it can be difficult to decide which is the most important. Children with oedema and high levels of ADH will have a serum osmolality less than 270 mmol/kg (with hyponatraemia) and a urine osmolality greater than 270 mmol/kg; the appropriate treatment is fluid restriction. On the other hand, in children with oedema due to capillary leak, fluid restriction and attempts to remove water (diuretics, dialysis) are unlikely to cure the oedema, and often cause hypovolaemia; in fact, large amounts of fluid (e.g. blood and normal saline) may be needed to preserve the intravascular volume in these children – the oedema will disappear only when the capillary damage resolves.

CRYSTALLOID OR COLLOID FLUIDS

There have been many reviews of the contentious issue of the relative merits of crystalloid or colloid fluids in critically ill patients. A widely quoted review

concluded that, compared with crystalloids, albumin increased mortality by 6% (95% CI, 3–9%).[40] However, a subsequent large study in 6997 adults in Australia found no significant difference in overall mortality between normal saline and 4% albumin[41] – the mortality with albumin tended to be lower in sepsis and higher in trauma, but the differences just failed to reach statistical significance in both subgroups. The Cochrane analysis is heavily influenced by the large Australian study, and it concluded that there is no evidence that albumin reduces mortality when compared with cheaper alternatives such as saline.[42]

There have been very few studies comparing crystalloid to colloid fluids in children, so most of the evidence comes from studies in adults. The use of albumin in paediatric and neonatal intensive care has been reviewed.[43,44] The meta-analyses do not suggest that colloid is better than crystalloid, and colloid is more expensive and carries a small risk of transmitting infection. Until more evidence is available, it seems sensible to use crystalloid as a routine, but give concentrated albumin to children with severe hypoalbuminaemia (perhaps if their serum albumin is less than 25 g/L) – unless the low albumin is caused by chronic malnutrition, when albumin should *not* be given.[45]

PARENTERAL NUTRITION

'Maintenance solution' is an unfortunate medical term, particularly when small children are concerned – a solution of 5% dextrose with sodium and potassium chloride provides maintenance amounts of water, sodium, potassium and chloride, but little or no calories, protein, trace elements or vitamins. For example, 100 mL/kg/day of 5% dextrose provides 20 Cal/kg/day (84 kJ/kg/day), which is only 20% of the requirement of a normal infant (let alone a child with increased calorie requirements). It has been estimated that, although an adult has the energy reserve to survive for about a year on 3 litres of 10% dextrose a day, a small preterm infant will survive only 11 days on 75 mL/kg/day of 10% dextrose.[50]

Many children in intensive care units are unable to absorb adequate amounts of food from the gut, and their nutritional reserves are small so they often need parenteral nutrition. However, parenteral nutrition is difficult to administer and dangerous in small children – such patients should be referred to a specialist paediatric unit as soon as possible.

The usual requirements for amino acids, dextrose and fat in parenteral nutrition in children are shown in Table 106.6. The amino acid solution can be mixed with dextrose in the pharmacy department to make a 'nutrient solution'. A standard nutrient solution might provide 4 mmol/kg/day of sodium, 3 mmol/kg/day of potassium, and 7.5 mmol/day of calcium and phosphate (with up to 12 mmol/L for neonates). The standard solution should also contain 4 mmol/L of magnesium, 0.2 μmol/kg/day of manganese, 3 μmol/kg/day of zinc, 0.5 μmol/kg/day of copper, 0.04 μmol/kg/day of iodide, 0.005 μmol/kg/day of chromium, 20 μg/L of hydroxycobalamin, 2 mg/L of phytomenadione, 1 mg/L of folic acid, and a multivitamin preparation. For short-term nutrition, the solution need not provide fluoride, iron or vitamins A, D and E, but a paediatric multivitamin preparation should be given to children on long-term parenteral nutrition. Fat can be given as a 20% emulsion, either through a separate i.v.

Table 106.6 Approximate requirements in paediatric parenteral nutrition

	TOTAL FLUID (ML/KG PER DAY)*	AMINO ACIDS (G/KG PER DAY)			DEXTROSE (G/KG PER DAY)			LIPID (G/KG PER DAY)				TOTAL CALORIES (KCAL) NEEDED (1 KCAL=4.2 KJ)†
		DAY			DAY			DAY				
		1	2	3+	1	2	3+	1	2	3	4+	
Neonates	100	1.5	2	2	10	10–15	15–20	1	2	2	2–3	100/kg
Under 10 kg	100	1.5	2	2	10	10	15–20	1	2	2	2–3	100/kg
10–15 kg	90	1	1.5	2	5	10	15	1	1.5	2	2–3	1000+(50/kg over 10 kg)
15–20 kg	80	1	1.5	1.5–2	5	10	10–15	1	1	1.5	2–3	1000+(50/kg over 10 kg)
20–30 kg	65	1	1	1–2	5	10	10–15	1	1	1	1–2	1500+(20/kg over 20 kg)
30–50 kg	50	1	1	1–2	5	5–10	10	1	1	1	1–2	1500+(20/kg over 20 kg)

*One mL/kg per day of fluid is needed for each kcal/kg per day; for adjustments to requirements, see Table 106.3 [Total kcal/kg per day equals g/kg per day of (amino acids×4)+(dextrose×4)+(fat×10). To calculate calories please note %=g/100 mL.]
†Calorie requirement of an active child in hospital.

line or alternating with the nutrient solution. Nutrient solutions for paediatric use contain high concentrations of calcium, magnesium and phosphorus and they should not be mixed with the fat emulsion, even in a Y-connection placed just before the cannula.

In a child on parenteral nutrition, it is important that abnormal fluid losses (Table 106.5) be replaced with an appropriate solution (in addition to the nutrient solution), and that parenteral nutrition always be introduced and withdrawn slowly. A dislodged i.v. cannula should be replaced immediately in a child on parenteral nutrition, to prevent rebound hypoglycaemia. If nutrient solution is not available at any time, it should be replaced with an infusion of a similar amount of dextrose (e.g. 20% dextrose with 40 mmol/L of sodium chloride and 20 mmol/L of potassium chloride).

Children receiving parenteral nutrition are liable to develop:

- hyperglycaemia (with glycosuria and dehydration)
- hypoglycaemia
- sepsis
- extravasation of solutions with necrosis of tissue
- thrombocytopenia
- hypoproteinaemia
- electrolyte imbalance
- acidosis
- anaemia
- hyperlipaemia
- uraemia
- cholestatic jaundice.

Frequent, careful monitoring is essential (**Box 106.2**). Initially, monitoring may need to be more frequent than suggested in Box 106.2, particularly in preterm babies. Monitoring can be less frequent once a child is stabilised on parenteral nutrition.

Box 106.2 Monitoring in paediatric parenteral nutrition

- Daily: inspect i.v. site, electrolytes, acid/base, serum triglyceride (reduce lipid infusion rate if triglyceride is greater than 2–2.5 mmol/L)
- Twice weekly: haemoglobin (transfuse if anaemia develops), platelets, proteins
- Weekly: creatinine, magnesium, calcium, phosphate, bilirubin, aspartate aminotransferase
- Blood glucose 8-hourly until the dextrose intake is stable
- Test urine for glucose 8-hourly (reduce dextrose intake if more than trace)
- Weigh frequently (daily if possible)

Sedation and analgesia in children

Geoff Knight

All children, including preterm infants, feel and remember pain and discomfort.[1] The provision of optimal levels of analgesia sedation should therefore be a priority in the management of all critically ill children.

Pain in the paediatric intensive care unit (PICU) may be surgical or procedural in origin (e.g. central venous catheterisation, lumbar puncture, removal of drains) or due to the patient's underlying illness. Sedation is frequently necessary to allow a child to tolerate an endotracheal tube and mechanical ventilation. It may also be needed to allow sleep in a brightly lit, noisy environment. As young children are unlikely to cooperate during investigations such as an echocardiogram or computed tomographic (CT) scan, sedation is often necessary to prevent excessive movement.

In addition to its humane benefits, sedation and analgesia can suppress non-advantageous physiological responses to noxious stimuli. Analgesic suppression of the marked post-surgery stress response has been associated with significant improvements in postoperative morbidity and mortality.[2–4]

ASSESSMENT

Adequacy of pain relief and sedation is dependent on the accuracy of the assessment of the degree of discomfort. This assessment is often difficult in the critically ill child who may be preverbal, developmentally delayed, intubated and/or paralysed, or simply uncooperative. Thorough assessment requires careful and frequent consideration of a number of factors. These include the nature of the noxious stimulus, variations in physiological parameters (e.g. heart rate and blood pressure) and interpretation of subjective clues (e.g. facial expressions and posture). Parental interpretations are a reliable adjunct and should be incorporated into the overall assessment.

Particular challenges in both pain and sedation assessments arise in a number of patient groups and validated assessment tools should be utilised whenever possible. Neonates and infants are particularly difficult to assess. The Premature Infant Pain Profile (PIPP) and CRIES scales are objective measures of pain in this group of patients.[5] For the equally problematic preverbal child the Multidimensional Assessment of Pain Scale (MAPS) is a useful validated tool for assessing postoperative pain.[6] Established assessment tools such as the Face, Legs, Activity, Cry and Consolability (FLACC) scale have been modified to enhance the pain assessment of children with cognitive impairment.[7] The COMFORT and the modified COMFORT 'Behavior' are validated observer-reported sedation scales for children 1–3 years.[8] In older children, self-reporting measurement scales can be used but these require a degree of patient cooperation.

The most challenging patients to manage optimally are those receiving muscle paralysis. Attempts to enhance the limited clinical parameters available for interpretation with an objective measure have centred on the bispectral index (BIS). Validation studies in the paediatric intensive care environment are, however, limited and highlight the probable inaccuracy of current methods of assessing sedation in this group.[9] In general it is preferable to err on the side of over- rather than undersedation in the paralysed patient.

MANAGEMENT

The management of discomfort, anxiety and pain should be multifaceted. Consensus guidelines from the United Kingdom Paediatric Intensive Care Society incorporate a detailed analysis of the evidence for various assessment and management strategies.[10]

Management should, whenever possible, begin prior to the child's admission to the intensive care unit. Orientation to the unit should be accompanied by a clear, age-appropriate explanation of the planned procedure or operation and the expected postoperative course. Parental presence during this phase and at other critical times is also important to help allay anxiety and fear. Close attention should also be paid throughout a child's admission to potentially distressing physiological factors, such as hunger and urinary retention. In addition to these supportive measures, many paediatric patients require a pharmacological form of analgesia or sedation.

Delivery of sedation and analgesia should be tailored to the patient's particular requirements. It is therefore essential that there be continuous assessment and frequent adjustment of therapy to ensure that optimal levels of sedation and adequate analgesia are delivered at all times. Nurse-titrated sedative and

Table 107.1 Single-dose and infusion rates of sedative and analgesic drugs*

DRUG	SINGLE DOSE	INTRAVENOUS INFUSION
Midazolam	0.1–0.2 mg/kg i.v. 0.5 mg/kg oral	50–200 μg/kg per hour
Ketamine	1–2 mg/kg i.v.	10–20 μg/kg per min (sedation) 4 μg/kg per min (analgesia)
Propofol	1–3 mg/kg i.v.	<4 mg/kg per hour (short term)
Clonidine	1–2 μg/kg i.v.	0.1–2 μg/kg per hour
Dexmedetomidine	0.5–1 μg/kg	0.2–1 μg/kg per hour (<24 hours)
Morphine	0.1–0.2 mg/kg i.v.	10–40 μg/kg per hour
Fentanyl	1–2 μg/kg i.v.	1–10 μg/kg per hour
Remifentanil	0.1–0.5 μg/kg i.v.	0.1–0.5 μg/kg per min

*Infusion rates are per hour except for fentanyl, remifentanil and ketamine (per minute).

analgesia regimens can optimise outcomes by allowing timely adjustments. This approach requires clear communication by medical staff of the aims of management, including the targeted level of sedation and clear understanding by nursing staff of the pharmacology of the agents being administered. Relief of pain should be achieved with analgesic agents and care must be taken to avoid excessive doses of sedative agents when the patient's primary need is for pain relief (**Table 107.1**). Although emphasis should be on achieving optimal comfort, consideration should also be given to minimising side-effects. A single drug may be effective but often a combination of medications and delivery methods (e.g. i.v./oral, i.v./epidural) will be useful and may avoid the side-effects of high doses of a single agent.

The differences in drug handling between children and adults should be considered when planning analgesia and sedation regimens. Drug distribution, rates of drug metabolism and relative organ blood flows differ in children, particularly in young infants. These differences may result in greater concentrations of free drug and differing volumes of distribution. Neonates have relatively larger total body water, extracellular fluid volume, blood volume and cardiac output and significantly less body fat than adults. Their blood–brain barrier is less efficient and allows more ready entry of some drugs to the brain. Mixed-function oxidases mature quickly to adult levels by 6 months of age, and acetylation and glucuronidation mechanisms mature by about 3 months. Renal blood flow and glomerular filtration rate are low in the immediate neonatal period. However, both increase significantly in the first 2–3 days and reach adult values by around 5 months. Tubular secretory capacity reaches adult levels by 6 months of age. In general, therefore, drug metabolism and clearance are relatively mature by 6 months of age, but great care is required when dealing with the neonate and young infant.

DRUGS

MIDAZOLAM

Midazolam is water-soluble, and has a rapid onset of action. Metabolism occurs in the liver and by 6 months of age is comparable to that of an adult. The standard i.v. sedative dose is 0.1–0.2 mg/kg and this is effective for uncomfortable procedures such as echocardiography and cardioversion. The oral route (0.5 mg/kg) may also be useful although there is a 15-minute delay to onset of sedation. Nasal administration (0.2 mg/kg) can be useful in children who do not have established i.v. access and in whom oral agents are not appropriate. Although midazolam may be effective as the sole sedative agent for ventilated patients, higher doses or additional agents are commonly required in young children (1–4 years)[11] – 50–200 μg/kg per hour, in combination with an opioid (morphine 10–40 μg/kg per hour), is generally effective in facilitating mechanical ventilation. Dose-related respiratory depression occurs and hypotension can be significant in hypovolaemic patients and in those with depressed myocardial function. During continuous infusion, accumulation can occur, particularly in young infants (under 6 months) and in patients with liver dysfunction.

Midazolam has been shown to induce neuronal apoptosis in animal models.[12] Alternatives, such as dexmedetomidine or fentanyl, should therefore be considered particularly in the neonate. Midazolam's use in neonatal intensive care is controversial because of concerns regarding both safety and effectiveness in the newborn.[13]

KETAMINE

Ketamine is a dissociative anaesthetic agent with sedative, analgesic and amnesic properties. Biotransformation occurs via the microsomal enzyme system. Thus, there is little metabolism in the newborn and clearance is less and elimination half-life greater in infants than in older children and adults.[14]

An i.v. dose of 1–2 mg/kg is usually adequate to induce deep sedation. Cardiovascular disturbance is minimal and ketamine is therefore particularly useful as the induction agent in status asthmaticus and in

patients with a compromised haemodynamic state, such as cardiac tamponade. Prolonged sedation for ventilated children can be achieved with a continuous infusion of 10–15 μg/kg per minute and analgesia can be provided by an infusion of 4 μg/kg per min. Concomitant use of an antisialogogue, such as glycopyrrolate, may help control the often seen increase in respiratory tract secretions. The unpleasant emergent phenomena seen frequently in adults probably occur less often in children. The traditional practice of concurrently administering a benzodiazepine with the aim of minimising these effects has minimal demonstrable benefit.[15] As with midazolam, ketamine has been shown to be neurotoxic in animal models and prolonged use in young infants should be minimised.[16]

PROPOFOL

Propofol is a rapidly acting hypnotic agent that is widely used in paediatric anaesthesia and in paediatric intensive care for short- and longer-term sedation.[17] Although it has no analgesic properties its short half-life makes it an attractive agent for sedation. The half-life decreases with age, probably owing to development of metabolising capacity and increasing hepatic flow.[18] Sedation can be achieved in the spontaneously breathing patient, with an induction dose of 1 mg/kg, followed by intermittent smaller doses; 2–3 mg/kg per hour has delivered uncomplicated satisfactory sedation to ventilated children.[19] Propofol should, however, be used with caution for sedation in the PICU because of the reported association between high-dose (>4 mg/kg per hour), prolonged (>29 hours) infusions and a clinical syndrome (propofol infusion syndrome) consisting of metabolic acidosis, lipaemia, cardiac failure, arrhythmias and death.[20] (It should be noted that the manufacturers advise against the use of propofol for sedation of children during intensive care.) The pathogenesis of this syndrome remains unclear, although it has been postulated that a disturbance of mitochondrial function leads to disordered hepatic lipid regulation.[21] Lipaemia may be an early indicator of developing problems and haemodialysis in the early phase is the only treatment described to date.[22]

There are sufficient concerns to limit the use of propofol in the PICU to short-term sedation in the stable ventilated child. A recent survey in Germany identified widespread use in paediatric intensive care with a time limitation of <24 hours in most cases and a median dose limit of 4 mg/kg/hour.[17] Limiting the duration of infusion to 6 hours at <4 mg/kg per hour is recommended. Use of propofol should also be avoided in the presence of shock, hypoxaemia or acute liver dysfunction.

CHLORAL HYDRATE

Chloral is an effective oral hypnotic and sedative agent with no analgesic effect. The hypnotic dose is 50 mg/kg and appropriate sedation may be achieved with lower doses. Gastric irritation can be a problem in some children. Toxic doses produce depression of respiration and cardiac contractility. Despite the disadvantage of delayed onset, chloral can be useful given prior to procedures, or as a supplemental sedative agent in the ventilated child, and it can effectively induce nocturnal sleep. On a cautionary note, there is some evidence that it may not be suitable in acutely wheezing infants.[23]

CLONIDINE AND DEXMEDETOMIDINE

Clonidine is an α_2-adrenoreceptor agonist with significant neurological, neuroendocrine and cardiovascular effects that result in sedation, analgesia and reduced sympathetic outflow. It is rapidly absorbed after oral administration and has a half-life of 9–12 hours. Metabolism is via the liver and kidney and approximately 50% is excreted unchanged in the urine. A single oral dose (4 μg/kg) can provide both preoperative sedation and postoperative analgesia following moderately painful surgery.[24] An i.v. infusion (0.1–2 μg/kg per hour) in combination with midazolam (50 μg/kg per hour) has been shown to produce effective sedation in ventilated children without haemodynamic disturbance.[25] Clonidine in similar doses can also have a role in the management of opioid withdrawal and in controlling the autonomic 'storms' seen following severe traumatic brain injury.

Dexmedetomidine is a selective α_2-agonist that has many of the properties of clonidine and may produce less respiratory depression. It is metabolised in the liver and the elimination half-life of 2 hours is similar in adults and older children and marginally longer in infants.[26] Retained respiratory drive during continuous infusion is particularly valuable and has allowed successful extubation of patients who had previously failed because of agitation.[27] The addition of dexmedetomidine to a sedative regimen has allowed a reduction in the required dose of benzodiazepines and opioids while delivering satisfactory levels of sedation with preserved respiratory drive.[28] Current licensing restrictions are for <24 hours' use in adults. The MIDEX and PRODEX trials assessed the efficacy of dexmedetomidine as an alternative to midazolam or propofol in adult intensive care patients.[29] Dexmedetomidine was comparable to both alternatives, and was associated with reduced ventilation time compared with midazolam. Studies in children are awaited, but dexmedetomidine is becoming accepted in the PICU as an adjunctive sedative agent (0.2–1 μg/kg per hour) and as an alternative to benzodiazepines.

Bradycardia and hypotension are seen with both clonidine and dexmedetomidine during continuous infusion and a risk–benefit assessment must be made prior to their use.

MORPHINE

Morphine is frequently used to provide analgesia and as part of a sedative regimen for children on mechanical ventilation. Marked variation in pharmacokinetics in

the neonatal period has been demonstrated, but infants over 1 month of age eliminate morphine efficiently and should not be more sensitive to respiratory depression than adults. Clearance and half-life (2 hours) are at adult values by 6 months of age.[30] The active metabolite is renally excreted and can therefore accumulate with renal impairment.

The standard i.v. dose is 0.1–0.2 mg/kg, and an infusion rate of 10–40 μg/kg per hour should be titrated to effect for postoperative pain relief in spontaneously breathing patients. With careful titration of dose to effect, higher rates can be administered, particularly to the child on mechanical ventilation. Patient-controlled analgesia devices delivering fixed doses of opioid, with or without a background infusion, can be used successfully by the majority of school-aged children and may occasionally be appropriate in intensive care. Histamine-related side-effects, in particular nasal itch, may warrant a change of opioid, and fentanyl is an alternative.

FENTANYL AND ALFENTANIL

Fentanyl has theoretical advantages over morphine in certain situations because of its rapid onset and its systemic and pulmonary haemodynamic stability. Termination of the effects of a single dose is by redistribution. Clearance is more rapid in neonates and infants compared with adults and does not change with time during continuous infusion. However, after prolonged infusion, unchanged fentanyl is returned to the circulation from peripheral compartments, resulting in a prolonged terminal elimination half-life of approximately 21 hours.[31]

The effective dose for painful procedures is 1–2 μg/kg. Fentanyl is useful as an anaesthetic agent in patients with labile pulmonary vasculature, as it can blunt changes in pulmonary vascular resistance seen with stimulation.[4] It does not, however, prevent the increase in pulmonary vascular pressure caused by hypoxia.[32] Infusions of 1–5 μg/kg per hour produce effective sedation in neonates on mechanical ventilation; 1–10 μg/kg per hour is required for analgesia in older children. Tolerance can develop rapidly in both neonates and older children.[33]

Alfentanil, because of its shorter duration of action, may have advantages for analgesia or sedation for very short procedures.

REMIFENTANIL

Remifentanil is a synthetic opioid with potent analgesic properties, rapid onset of action and, following initial redistribution, a short half-life of around 8 minutes. Metabolism occurs via non-specific esterases and is therefore relatively independent of renal and hepatic mechanisms. The short duration of action allows rapid emergence from general anaesthesia, thereby facilitating extubation or assessment of the patient's neurological state.[34] Postoperative pain needs to be managed with an alternative analgesic regimen and a longer-acting opioid (morphine) should be administered prior to discontinuing remifentanil.

Infusions of 0.1–0.5 μg/kg per minute have produced satisfactory analgesia and sedation in ventilated adult patients and there is evidence that ventilation times are shorter and weaning from ventilation more rapid in comparison to standard sedation regimens.[35] Although remifentanil is widely used in paediatric anaesthesia there are few data available on its use in children in intensive care. Uncomplicated and successful use in the induction and sedation of a ventilated preterm neonate has been described.[36] As metabolism is relatively independent of renal and hepatic mechanisms, remifentanil could be considered for use in patients with liver and/or renal impairment who would not have continuing pain and in whom rapid termination of sedation is required.

THIOPENTAL

Thiopental is useful as an anaesthetic induction agent in critically ill children, although its hypotensive effects limit its use in shocked patients. The standard dose is 5 mg/kg, and this should be reduced to 2–3 mg/kg when there is a risk of hypotension. Thiopental is useful in the management of refractory status epilepticus and may have a role in difficult cases of raised intracranial pressure. In such cases, it is administered by continuous infusion (1–5 mg/kg per hour). Accumulation can lead to prolonged sedation.

PARACETAMOL AND NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

The addition to an analgesic regimen of either paracetamol or a non-steroidal anti-inflammatory drug (NSAID) should be considered provided there are no contraindications.

Paracetamol is useful for mild to moderate pain and is an effective supplement to opioids for more severe pain. Enteral preparations, though useful, are prone to erratic absorption. The intravenous preparation is more useful in the intensive care setting and has been shown to reduce opioid requirements in adults with few side-effects following orthopaedic surgery.[37] The recommended initial i.v. dose in children is 15 mg/kg and the total daily i.v. dose should be limited to 60 mg/kg. Lower i.v. doses (7.5 mg/kg 6-hourly) are recommended for infants <10 kg. Contraindications to paracetamol include liver dysfunction, and care must be taken with dosage to avoid liver injury in all children.

NSAIDs should also be considered as supplemental analgesics. Care should be taken, however, regarding the risk of bleeding, particularly in the postoperative period and in the highly stressed patient in whom gastric bleeding is more likely. Ketorolac (0.6 mg/kg) can be given i.v. and therefore has the potential to reduce the dose of opioid required in the immediate postoperative period when enteral medications are not appropriate.

NITROUS OXIDE

Nitrous oxide is a potent analgesic agent. It is useful in intensive care during short painful procedures such as removal of surgical drains. A mixture of 50% nitrous oxide with oxygen provides analgesia in awake and cooperative patients. It is unsuitable for repeated or continuous use because of toxicity, and administration to younger children may cause distress because of the need for application of a mask.

ISOFLURANE

Isoflurane has been used for long-term sedation in intensive care in adults. As elimination is independent of hepatic and renal mechanisms, there are theoretical advantages in many critically ill patients. However, an association between isoflurane sedation and neurological abnormalities has been reported in children.[38] These abnormalities, including ataxia, agitation, hallucination and confusion, although all reversible by 72 hours, were a considerable clinical problem. They make this technique unsuitable in the PICU.

WITHDRAWAL SYNDROMES

Opioid withdrawal is a well-recognised problem and symptoms include poor feeding, tremors, agitation, poor sleeping, tachycardia, diarrhoea, sweating, increased muscle tone, dystonic posturing and seizures. Withdrawal occurs particularly following prolonged high-dose infusions. The risk of withdrawal following a fentanyl infusion is associated with the duration of infusion and the total dose. Infusion for >5 days or a total dose >1.5 mg/kg is associated with a greater than 50% incidence of withdrawal.[39] Benzodiazepine withdrawal (agitation, anxiety, sweating, tremor) is also seen and the risk following a midazolam infusion is associated with a total dose >60 mg/kg.[40]

Careful attention to weaning an infusion in high-risk patients can minimise withdrawal symptoms. Longer-term pharmacological management is occasionally required and is best managed by administering the agent from which the patient is withdrawing. Tapered infusions can be substituted for by enteral morphine, methadone or diazepam and clonidine has also been utilised.[41] The weaning programme can be as short as 5 days.[42]

Assessment is difficult but is assisted by the use of a validated assessment tool; the Withdrawal Assessment Tool-1 (WAT-1) is a promising assessment instrument.[43] Although withdrawal can be a significant problem, adequate sedation or analgesia should not be withheld because of fears of the development of drug dependence.

LOCAL ANAESTHESIA

Local anaesthesia can produce effective analgesia without systemic effects and therefore has significant advantages in many patients, particularly the postoperative group. In the intensive care setting, it can be used as the sole method of providing analgesia or in combination with i.v. agents. The risk of toxicity is related both to the dose and to the rapidity of absorption, which is dependent on local blood flow. Metabolism of the amide local anaesthetics (lidocaine, bupivacaine) is via the cytochrome P-450 system and their half-life is longer in infants less than 6 months of age. Unbound drug does not produce analgesia but is potentially toxic as infants have lower levels of the binding protein α-glycoprotein. The use of local anaesthesia in infancy therefore requires careful assessment and close monitoring.

TOPICAL

Analgesia for some painful procedures is possible with minimal sedation using topical preparations or careful local infiltration. The total dose of local anaesthetic agent infiltrated must be monitored to ensure that maximum doses are not exceeded. The total dose of lidocaine should not exceed 4 mg/kg (7 mg/kg if combined with epinephrine (adrenaline)). Systemic absorption of the prilocaine component in topical preparations occurs and neonates, because of their relative deficiency of methaemoglobin reductase, are at particular risk of methaemoglobinaemia. Topical preparations should be used with caution in this group.

NERVE BLOCK

Femoral nerve blockade is a simple technique that produces effective analgesia in cases of femoral shaft fracture. A single injection is effective for approximately 3 hours and longer-term analgesia can be provided by a continuous infusion of bupivacaine (0.125%) at 0.2–0.3 mL/kg per hour through a fine catheter placed adjacent to the femoral nerve.[44] As this technique can decrease opioid requirements, it is particularly useful in trauma patients who have suffered a coexistent head injury.

Intercostal nerve blocks may be useful after thoracotomies and liver transplants in children.[45] A single dose of 0.125% bupivacaine (maximum single dose 2 mg/kg) can produce up to 8 hours of analgesia. The dose must be carefully monitored, because the relatively high blood flow to the area increases the risk of toxicity. Continuous infusions via an intercostal catheter can provide ongoing pain relief. There is a risk of pneumothorax with this technique and it should therefore be avoided when there is significant coexistent lung disease.

EPIDURAL

Caudal, lumbar and thoracic epidural anaesthesia can provide effective control of postoperative pain in children.[46,47] The procedures must be performed by skilled experienced staff who clearly understand the risks and benefits. A complication rate of 1.5 per 1000 has been

reported, with dural puncture and intravascular injection seen most commonly.[48] Other risks include cord injury, epidural infection and excessive motor blockade. Infants under 6 months are at highest risk because of their size and immature metabolism of local anaesthetic agents.

Many epidural catheter insertions are performed in the operating theatre as general anaesthesia is a prerequisite in most paediatric patients. PICU care may subsequently be required because of the nature of the surgery (e.g. thoracotomy, liver transplant) or because of underlying patient factors (e.g. neurological disorders, morbid obesity, age). Epidurals have been used in paediatric cardiac surgery without a clear benefit over conventional postoperative analgesia.[49] Particular indications for commencing epidural analgesia in the PICU include burns in a suitable distribution (e.g. abdomen and lower limbs) and blunt chest trauma with rib fractures. Contraindications include shock, hypovolaemia, meningitis, coagulopathy and local skin infection.

Bupivacaine is the most commonly used local anaesthetic. A single dose should not exceed 2.5 mg/kg and the maximum infusion rate is 0.4 mg/kg per hour (0.2 mg/kg per hour in infants). Opioids (morphine and fentanyl) may be added and have a synergistic effect, thereby allowing less local anaesthetic agent to be used. However, epidural opioids can cause sedation and respiratory depression.

SUMMARY

Delivering optimal levels of analgesia and sedation in the paediatric intensive care unit is challenging and requires careful assessment and a management approach incorporating both pharmacological and non-pharmacological aspects. Use of age-appropriate validated assessment tools combined with continuous adjustment of drug delivery is required. Withdrawal is common in children but the risk should not impact on the delivery of effective sedation or analgesia. Alternatives to the conventional approaches are required at times and the PICU team should be open to novel drug therapies or methods of drug delivery.

Shock and cardiac disease

Johnny Millar

SHOCK

Shock is the clinical state resulting from insufficient oxygen delivery to meet oxygen demand, described in detail in Chapter 15. Shock in children is most commonly due to hypovolaemia or sepsis and remains an important cause of global infant and child mortality. The cellular effects of tissue hypoxia in shock are the same in children and adults, but there are important developmental changes in anatomy, physiology and immunity during childhood that influence the incidence, presentation and natural history of shock.

DEVELOPMENTAL DIFFERENCES

BODY FLUID COMPARTMENTS[1]

Although the extracellular fluid volume in children is greater than in adults when indexed to body weight, the small absolute volumes involved are critical when blood or fluid loss causes shock; 100 mL blood loss is inconsequential for an adult, but represents one-third of the blood volume for a neonate (**Table 108.1**).[1]

CARDIAC[2–4]

There are many differences between the newborn and the mature heart that have important effects on function, particularly under stress. The newborn heart has a relatively small left ventricular muscle mass that must cope with the newly imposed demands of the systemic circulation. In response to increased afterload, the neonatal myocardium increases in mass by both hypertrophy and hyperplasia, with the capacity for the latter of these mechanisms being lost after the first 6 months of life. Neonatal cardiac myocytes appear small and blunted with a higher proportion of non-contractile elements than mature myocytes. The fewer myofibrils are poorly aligned and there are sparser, disorganised-looking mitochondria. Less efficient handling of calcium by the myocyte membrane and sarcoplasmic reticulum make the neonatal myocyte more dependent on extracellular fluid calcium concentration, which may contribute to limited cardiac reserve.

The physiological consequence is a stiffer, less compliant ventricle that is less able to generate contractile force. Physiological changes at birth (see below) increase both volume and pressure load to the left ventricle. The ability of the ventricle to increase output in response to further volume or pressure loading is limited. The neonatal heart functions at a high state of beta-adrenergic stimulation and therefore has a restricted capacity to increase contractility and rate. Following birth there is a steady increase in stroke volume index and cardiac index over the first 3 years of life.

VASCULAR

Antenatal pulmonary blood flow is low (<10% of combined ventricular output) through a relatively muscularised high-resistance circulation. Blood ejected by the right ventricle is mostly diverted through the ductus arteriosus to the systemic circulation. Pulmonary vascular resistance (PVR) falls abruptly at birth with a concomitant increase in pulmonary blood flow. The PVR then falls more slowly, reaching adult levels over the next 6 weeks as a result of pulmonary vascular remodelling. The increase in pulmonary blood flow immediately following birth results in increased preload to the left ventricle. Coincident with this the systemic vascular resistance rises acutely. Following the transition from fetal to neonatal circulation, systemic vascular resistance index remains relatively constant throughout early childhood.[5]

MICROCIRCULATION

There are animal and human data to support the notion of maturation of the microcirculation.[6,7] The infant and young child's microcirculation is leakier at baseline and functions at a higher turnover of fluid and protein than the adult. This state of higher turnover may predispose the child to greater capillary leak in response to inflammatory and traumatic stimuli resulting in hypovolaemic shock.

IMMUNITY AND THE INFLAMMATORY RESPONSE[8]

The newborn has had little prior exposure to pathogens and has limited capacity to respond to infection, so is at increased risk of invasive infection. This risk persists beyond the newborn period as the immune system

Table 108.1 Body fluid compartments during childhood (mL/kg)[1]

AGE	TOTAL BODY WATER	EXTRACELLULAR FLUID	INTRACELLULAR FLUID	BLOOD
Pre-term newborn	800	550	300	95
Birth	750	450	300	85
1 year	700	350	350	80
5 years	650	250	400	75
Adult	600	200	400	70

remains immature through infancy and early childhood, with deficits in both innate and adaptive immunity. In addition to immature barriers to infection, infants have lower levels of circulating complement components and defective natural killer cell function. A mature pattern of cytokine and chemokine production is not attained until later in childhood. B cells are geared toward producing IgM rather than IgG or IgA and there are multiple distinct deficiencies in T-cell function. The inflammatory response to sepsis also appears to undergo complex developmental changes, the implications of which are hard to define. Aspects of the pro- and anti-inflammatory response are qualitatively and quantitatively different in children compared with adults, including a relative exaggeration of the anti-inflammatory response.

Like adults, children are placed at risk of infection by therapeutic immunosuppression but there are also a large number of congenital diseases that are characterised by generalised or specific defects in immune function.

RECOGNITION OF SHOCK

Recognition of early shock is very important as children compensate well initially, but their capacity to do so is rapidly exhausted and decompensation can then be sudden; during the early stages of compensated shock in infants, signs may be limited to tachycardia and tachypnoea (**Table 108.2**). Hypotension is a late finding and demands urgent attention.

Table 108.2 95% ranges for heart rate, blood pressure and respiratory rate in childhood[48]

AGE	HEART RATE (BEATS PER MINUTE)	MEAN BLOOD PRESSURE (mmHg)	RESPIRATORY RATE (BREATHS PER MINUTE)
Birth	95–145	40–60	30–66
6 months	110–175	50–90	28–57
1 year	105–170	50–100	25–55
4 years	81–131	50–100	20–26
7 years	66–111	60–90	20–24
14 years	56–106	65–95	15–20

INITIAL ASSESSMENT AND INVESTIGATION

HISTORY

- Fever, feeding, urine output, diarrhoea, vomiting
- Rapid breathing, sweating, tiring while feeding
- Irritability, lethargy
- Trauma
- Potential for trauma in infants
- Potential for ingestion
- Vaccination history.

EXAMINATION

- Temperature
- Conscious level
- Peripheral perfusion, capillary refill
- Rash
- Skin turgor
- Mucous membranes
- Pulses
- Heart rate, rhythm
- Blood pressure
- Respiratory rate.

INITIAL INVESTIGATIONS

- Chest X-ray
- Arterial blood gas, lactate
- Full blood count and film examination
- Blood glucose
- Plasma electrolytes, urea, creatinine, liver function tests.

If there is evidence of sepsis or if there is no obvious cause for shock take cultures and start antibiotic therapy (**Table 108.3**).[9–11]

- Blood cultures – peripheral blood and from any lines already in place
- Urine cultures (suprapubic aspirate or in–out urinary catheter in young infants)
- Throat swab
- Urine, stool and nasopharyngeal aspirate for virology
- Do not do a lumbar puncture in a shocked child. Commence antibiotics following other cultures. CSF for bacterial and viral culture and PCR can be obtained later.

Table 108.3 Initial antibiotic treatment of septic shock in children

FIRST FEW DAYS OF LIFE	
Benzylpenicillin	60 mg/kg 12-hourly
Gentamicin	5 mg/kg 36-hourly
BEYOND FIRST FEW DAYS OF LIFE	
Flucloxacillin	50 mg/kg 6-hourly
Cefotaxime	50 mg/kg 6-hourly
Gentamicin	6 mg/kg 24-hourly
IF HOSPITAL ACQUIRED, REPLACE FLUCLOXACILLIN WITH	
Vancomycin	25 mg/kg load then 15–20 mg/kg 8-hourly

TYPES OF SHOCK

The traditional classification of shock (Ch. 15) is valid in children, but a combination of these is likely to be present in any given clinical situation. In particular it is best to think of septic shock as a clinical entity that incorporates features of several shock types.

HYPOVOLAEMIC SHOCK

This is a common presentation in childhood, particularly secondary to water and electrolyte losses with diarrhoea and vomiting.

The initial compensatory response to hypovolaemia is an increase in catecholamine secretion, leading to poor peripheral perfusion, tachycardia and a normal blood pressure with diminished pulse pressure. Lethargy and tachypnoea secondary to increasing metabolic acidosis are variably present. Up to 15–20% of the circulating blood volume may be lost before hypotension occurs. With further volume loss end-organ perfusion and oxygen delivery are compromised leading to worsening acidosis, coma, oligo/anuria and ultimately myocardial dysfunction.

The cause of hypovolaemia is usually evident from the history and examination, but hidden blood loss must be considered, particularly in infants where unreported head or abdominal trauma may have occurred with few external signs.

TREATMENT

Ensure adequate airway protection and breathing and administer oxygen. After establishment of intravenous (or intraosseous) access, early and aggressive intravenous fluid resuscitation is vital to restore the circulating blood volume. Give fluid (10–20 mL/kg 0.9% NaCl) rapidly with frequent clinical reassessment to verify signs of reversal of shock. Give blood if shock is due to ongoing blood loss.

CARDIOGENIC SHOCK

See section on Cardiac disease below.

DISTRIBUTIVE SHOCK

CAUSES

These include anaphylaxis, spinal cord injury or administration of vasodilators. Septic shock in children may have a distributive component, but this is not as common a finding as in adults (see below).

PRESENTATION

In distributive shock tissue perfusion is inadequate despite an initially normal circulating blood volume and normal (or high) cardiac output. Abnormal vasomotor tone with profound vasodilatation leads to a reflex tachycardia (in spinal cord injury absence of sympathetic activity may result in bradycardia). Examination reveals warm peripheries, tachycardia and hypotension with a wide pulse pressure. The cause of distributive shock is likely to be clear from clinical examination.

TREATMENT

Attend to airway and breathing, obtain intravenous access and give rapid fluid boluses (20 mL/kg 0.9% NaCl). If there is inadequate reversal of shock then vasopressors may be necessary to restore blood pressure (or counteract the effects of vasodilator drugs).

Anaphylaxis must be treated specifically and urgently. **Table 108.4** gives paediatric epinephrine (adrenaline) doses.

OBSTRUCTIVE SHOCK

CAUSES

These include pericardial tamponade, tension pneumothorax and mediastinal mass.

PRESENTATION

In obstructive shock extracardiac restriction of cardiac output prevents adequate oxygen delivery. There may be obstruction to the pulmonary or systemic outflow tract or circulation, or compression by pericardial tamponade or tension pneumothorax.

TREATMENT

Treatment is aimed at ensuring adequate circulating volume and identifying and remedying the cause of the obstruction. Tamponade and tension pneumothorax require urgent drainage.

SEPTIC SHOCK[8,12–14]

The clinical presentation of septic shock in young children is different to adults, who reliably present with peripheral vasodilation, hypotension and a relatively high cardiac output (‘warm shock’). In children the

Table 108.4 Paediatric cardiac drug doses[48]

DRUG	DOSE
Adenosine	0.1 mg/kg (max 3 mg); increase by 0.1 mg/kg/dose to 0.3 mg/kg (max 12 mg)
Alprostadil (PGE_1)	10–50 ng/kg/min
Amiodarone	25 µg/kg/min for 4 h, then 5–15 µg/kg/min
Atropine	0.02 mg/kg (max 0.6 mg)
Bicarbonate (10%$NaHCO_3$)	1–2 mL/kg
Digoxin	15 µg/kg, then 5 µg/kg after 4 hours, then 3–5 µg/kg 12-hourly
Dobutamine	2–10 µg/kg/min
Epinephrine	
bolus	10 µg/kg (0.1 mL/kg 1 : 10 000)
infusion	0.05–0.5 µg/kg/min
anaphylaxis	10 µg/kg (0.01 mL/kg 1 : 1000) by deep i.m. injection
Esmolol	500 µg/kg over 1 min, then 25–250 µg/kg/min
Isoproterenol	0.05–0.5 µg/kg/min
Levosimendan	12.5 µg/kg over 10 min, then 0.2 µg/kg/min for 24 h
Metaraminol	
bolus	0.01 mg/kg
infusion	0.05–0.5 µg/kg/min
Metoprolol	0.1 mg/kg over 5 min (max 5 mg)
Midazolam	
bolus	0.1 mg/kg
infusion	1–4 µg/kg/min
Milrinone	0.25–0.75 µg/kg/min
Morphine	
bolus	0.1 mg/kg
infusion	10–60 µg/kg/hour
Nitric oxide (inhaled)	10–20 parts per million
Norepinephrine	0.05–0.5 µg/kg/min
Sodium nitroprusside	0.5–3 µg/kg/min
Vasopressin	0.0005–0.002 U/kg/min

picture is usually dominated by myocardial suppression and peripheral vasoconstriction ('cold shock'). Hypovolaemia occurs rapidly due to capillary leak secondary to the sepsis-induced inflammatory response. Septic shock in children may be difficult to distinguish from cardiogenic shock or hypovolaemic shock. Neonatal sepsis often presents with features of persistent pulmonary hypertension, with right heart failure and a degree of cyanosis depending on patency of the ductus arteriosus and foramen ovale.

TREATMENT[13,15]

Recent guidelines emphasise the importance of prompt and aggressive fluid resuscitation and early institution of inotropic therapy.[13]

Airway

Administer supplemental oxygen to all children with shock. Intubate patients who are unable to protect their airway or have impending respiratory failure.

Circulation and access (see Ch. 105)

If peripheral access is difficult and the child is obtunded or severely shocked consider intraosseous access early. Give fluid boluses (20 mL/kg 0.9% NaCl) to restore circulating blood volume. Children with septic shock often require large amounts of fluid resuscitation – occasionally more than 100 mL/kg. In patients who do not have reversal of signs following 60 mL/kg of fluid, gain central venous access. This allows measurement of central venous pressure, administration of inotropes or vasoconstrictors and measurement of central venous saturation (see below). Insert an arterial line for frequent sampling and invasive monitoring of blood pressure.

Echocardiography is an important means of guiding inotrope and vasopressor management, allowing assessment of cardiac filling, contractility and PVR. Invasive measurement of cardiac output is rarely performed in children; pulmonary artery catheter insertion is technically difficult and although several non-invasive methods are available to estimate cardiac output in children none are widely used.

Inotrope/vasodilator/vasoconstrictor therapy (see Table 108.4 for drug doses)

Do not delay starting vasoactive drugs if there is difficulty gaining central venous access. Dilute infusions of inotropes and vasoconstrictors may be administered through a peripheral line, with care taken to avoid and check for extravasation.

Decreased contractility on echo or clinical suspicion

Dobutamine is a useful first-line inotrope in children and is relatively safe to administer through a peripheral intravenous line. Although dopamine is still widely used, it inhibits anterior pituitary release of thyrotropin, growth hormone and prolactin[16] and may be relatively ineffective in young infants. Epinephrine should be started as a second-line drug if cardiac function remains inadequate despite dobutamine.

Hypotension and warm peripheries

A vasoconstrictor may be used alone if myocardial function is adequate or is added to an inotrope if contractility is poor. Norepinephrine is the drug of choice,

but an inadequate response to it may be due to downregulation of catecholamine receptor numbers or function. Apparent norepinephrine resistance warrants a trial of vasopressin, but a randomised controlled trial in paediatric shock failed to demonstrate any outcome benefit with vasopressin treatment (and showed a trend towards increased mortality).[17]

Hypotension and cool peripheries

Treat decreased contractility as above. As discussed earlier, peripheral vasoconstriction is a compensatory mechanism to maintain adequate perfusion pressure. Do not add a vasodilator to an already hypotensive patient. A vasoconstrictor may be needed in addition to an inotrope if hypotension persists.

Normotension and cool peripheries

If blood pressure is normal or high, addition of a vasodilator may reduce afterload and improve cardiac output. Sodium nitroprusside (SNP) has a short half-life and can be discontinued rapidly if the blood pressure falls. In addition to being a powerful vasodilator, milrinone has inotropic effects but should be used with care because of its relatively long half-life.

Pulmonary hypertension

If there is evidence of pulmonary hypertension during shock start an inotrope (dobutamine or epinephrine) to support the right ventricle. Intubate (if not already done), ventilate using a high Fi_{O_2} to a normal Pa_{CO_2} and correct acidosis. Inhaled nitric oxide should be added to reduce PVR.

Antibiotics

Early and appropriate antibiotic therapy is associated with improved survival.[18] Administer antibiotics to patients in whom the cause of shock is not immediately apparent. After appropriate cultures, selection of antimicrobials is guided by the clinical picture including any available results from prior cultures. In the absence of specific information, a suggested first-line treatment schedule is shown in Table 108.3. A search for the source or site of infection should be undertaken and it may be necessary to drain collections or remove infected tissue.

Blood transfusion

Transfusion of packed red cells to replace blood loss is essential. In a patient with ongoing evidence of inadequate oxygen delivery there is some evidence to support transfusion to maintain a haemoglobin of >10 g/L, particularly in septic shock.[13]

Corticosteroids

Give hydrocortisone to shocked patients who are at risk of absolute adrenal insufficiency (recent or ongoing treatment with corticosteroids, known hypothalamic/pituitary/adrenal disease or purpura fulminans). The routine use of hydrocortisone in septic shock does not reduce mortality in adults, although there may be some benefit to a prolonged low-dose course.[19] In children there is less evidence on which to base a recommendation and this remains a controversial area.[13,15]

Intravenous immunoglobulin

Intravenous pooled immunoglobulin (IVIG) has been used in both children and adults with septic shock, but evidence for an effect on mortality is poor.[20] IVIG has the potential to neutralise superantigens in toxic shock syndrome and its use is often recommended in this setting, but again clear evidence regarding clinical efficacy is lacking.[21] Anticytokine and antiendotoxin monoclonal immunoglobulin therapies remain experimental.

Extracorporeal membrane oxygenation (ECMO)

Current guidelines recommend ECMO for refractory septic shock.[13,15] There is emerging evidence that central ECMO cannulation via sternotomy is superior to peripheral or neck cannulation paediatric sepsis, allowing insertion of larger cannulae and consequently higher ECMO flows.[22]

Insulin

Hyperglycaemia is common in shock and may be exacerbated by epinephrine and corticosteroid treatment. Treat sustained hyperglycaemia with insulin infusion, but critically ill children are relatively sensitive to insulin[23] and have limited metabolic reserve, increasing the risk of hypoglycaemia. There is conflicting evidence regarding the benefits of tight glycaemic control in children and neonates, and hypoglycaemia has been a significant problem in many of these studies.[24–27]

GOALS OF TREATMENT

The goals of treatment are to reverse the shock state and ensure ongoing adequate tissue oxygen delivery. Frequent clinical reassessment is aided by laboratory investigations including:

- *heart rate:* normal for age (see Table 108.2)
- *blood pressure:* normal for age (see Table 108.2)
- *central venous pressure:* 10–12 mmHg (1.33–1.96 kPa)
- *central capillary refill:* <3 seconds
- *mental state:* normal
- *urine output:* >0.5 mL/kg/h
- *serum lactate:* <2.0 mmol/L
- *central venous saturation:* >70%.

Plasma lactate concentrations are indicative of inadequate tissue oxygenation and therefore a useful marker of shock. Hyperlactaemia can also be due to dead gut, liver dysfunction or epinephrine infusion.[28]

Measurement of central venous saturation (Scv_{O_2}) can be used to assess adequacy of oxygen delivery in the absence of a pulmonary artery catheter.[29] A sample taken from the superior vena cava (SVC) or SVC/RA

(right atrium) junction is best; sampling from within the right atrium may be polluted by poorly saturated blood from the coronary sinus or by interatrial shunting. Goal-directed treatment of septic shock in children with a target Scv_{O_2}>70% is associated with improved survival.[30] In children with structural heart disease and intracardiac mixing, aim for an Sa_{O_2} – Scv_{O_2} difference of ≤30%.

CARDIAC DISEASE

Appropriate drug doses for this section are given in Table 108.4.

CARDIOGENIC SHOCK

Cardiogenic shock can be difficult to distinguish from septic shock. Causes of cardiogenic shock are listed in **Box 108.1**.

Patients present with tachycardia, low pulse volume and poor peripheral perfusion as vasoconstriction maintains blood pressure in the initial stages. Tachypnoea, obtundation and decreased urine output are present early. Examination may reveal a gallop rhythm, hepatomegaly, sweating and peripheral oedema. The presence or absence of a cardiac murmur is unlikely to be helpful in acute diagnosis. Ongoing shock leads to progressive hypoperfusion of end organs.

INVESTIGATION

Initial investigations include chest X-ray, ECG and echocardiogram, with further tests prompted by individual findings. Take blood cultures and start antibiotics if there is no known cause for cardiogenic shock.

Box 108.1 Causes of cardiogenic shock

- Primary cardiac disease
  - Congenital heart disease
  - Post cardiac surgery
  - Cardiac trauma
  - Myocarditis
  - Cardiomyopathy
  - Arrhythmias and conduction defects
  - Endocarditis
- Local disease with cardiac effects
  - Constrictive pericarditis
  - Pericardial tamponade
  - Compression of heart by tumour, tension pneumothorax
- Systemic disease with cardiac effects
  - Sepsis
  - Hypoxic ischaemic injury
  - Autoimmune disease
  - Kawasaki disease
  - Drug ingestion

TREATMENT

Treat as described for septic shock in the preceding section (see Table 108.4).

Consider ECMO early if the patient is deteriorating or unresponsive to therapy.

CARDIAC FAILURE

Children with heart failure are a diverse group of patients with a heterogeneous group of diseases leading to worsening heart function. Cardiac failure can be due to primary or secondary myocardial disease, or the effects of congenital heart disease or its treatment (**Table 108.5**).

INVESTIGATIONS

- Chest X-ray
- Electrocardiogram
- Echocardiogram
- Further imaging with CT, MRI and catheter may be warranted
- Blood gas
- Electrolytes, renal and liver function
- Coagulation
- BNP, troponin I
- Viral cultures – urine, stool and nasopharyngeal aspirate
- Serum amino acids
- Urine amino and organic acids
- Serum carnitine.

TREATMENT

Treat any identified underlying cause for heart failure (sepsis, correctable congenital heart disease, arrhythmias, anaemia). Further treatment is in the following sections on cardiomyopathy, congenital heart disease and disorders of cardiac rhythm.

CARDIOMYOPATHY[34,35]

Primary cardiomyopathy is rare in childhood (1.13–1.24 per 100 000 children per year) with the highest incidence in the first year of life. Dilated and hypertrophic cardiomyopathies account for the majority (~80%) of cases and most do not have an identifiable cause. There is considerable phenotypic overlap between the different types of cardiomyopathy, and the clinical presentation is usually congestive cardiac failure. The 5-year mortality or transplant rate for children with dilated cardiomyopathy is 46%, with younger children and those who are sickest at presentation being at highest risk.

Infants present with poor feeding and failure to thrive, along with tachycardia, tachypnoea and sweating. There may be a hyperdynamic precordium and a gallop rhythm. In older children a careful history will often elicit decreased physical activity in comparison to their peers for many months. The clinical

Table 108.5 Causes of heart failure in children

CAUSE	EXAMPLES
BIRTH–2 WEEKS	
Sepsis	Neonatal sepsis, group B *Streptococcus*
Hypoxic ischaemic injury	Birth asphyxia
SVT	Congenital/neonatal
Congenital heart block	Isolated or with structural heart disease
Arteriovenous malformations	Vein of Galen malformation
Duct-dependent systemic circulation	Aortic coarctation or stenosis, HLHS
Persistent pulmonary hypertension of newborn	Secondary to sepsis, hypoxic ischaemic injury etc.
Anaemia	Twin-to-twin transfusion, Rhesus incompatibility
Cardiomyopathy	Infant of diabetic mother, congenital
Neonatal myocarditis	Enterovirus
Cardiac tumour	Rhabdomyoma
2 WEEKS–6 MONTHS	
Large volume left to right shunt lesions	VSD, AVSD, truncus arteriosus, AP window
Cardiomyopathy, myocarditis	
Coronary lesion	ALCAPA
Metabolic	Hypothyroidism
LATER CHILDHOOD	
Unrepaired congenital heart disease	
Left ventricular failure	Left to right shunt lesions Aortic or mitral valve disease
Right ventricular failure	Pulmonary or tricuspid valve disease Pulmonary hypertension
Systemic right ventricular failure	Congenitally corrected transposition
Operated congenital heart disease	
Left ventricular failure	Residual aortic or mitral valve disease Subaortic stenosis
Right ventricular failure	Pulmonary valve disease (repaired TOF) Pulmonary hypertension
Systemic right ventricular failure	Post Senning or Mustard
Single ventricular failure	Post aortopulmonary shunt, Glenn or Fontan
Arrhythmia	Post Fontan, Senning, Mustard
Cardiomyopathy, myocarditis	
Acquired cardiac disease	Rheumatic heart disease, endocarditis, Marfan syndrome, cor pulmonale
Transplant rejection	

HLHS=hypoplastic left heart syndrome; VSD=ventricular septal defect; AVSD=atrioventricular septal defect; AP=aorto-pulmonary; ALCAPA=anomalous origin of left coronary artery from pulmonary artery; TOF=tetralogy of Fallot.

presentation becomes more like that seen in adults, with hepatomegaly, ascites, oedema and poor peripheral perfusion.

TREATMENT (SEE TABLE 108.4 FOR DRUG DOSES)

There are few data on which to base treatment of heart failure in children. Mainstays of chronic treatment are diuretic therapy and ACE inhibitors, or beta blockers. The sicker child in the ICU will require further measures.

Oxygen

Treat decompensated heart failure with facemask oxygen.

Ventilation

Intubation and positive-pressure ventilation improve gas exchange and reduce work of breathing. Although positive pressure probably has no direct effect on left ventricular contractility, it improves output by reducing left ventricular afterload.[36] High pressures may impair cardiac output by reducing preload and increasing afterload to the right ventricle.

Afterload reduction

Vasodilator therapy is useful as long as an adequate blood pressure can be maintained. Sodium nitroprusside is a potent pure vasodilator. Milrinone has the additional advantage of some inotropic and lusitropic effects.

Inotropes

Dobutamine or milrinone (if vasodilatation is tolerated) can be used as first-line agents. Despite limited data in children, levosimendan is being used increasingly in paediatric heart failure. It appears capable of increasing cardiac output at minimal metabolic cost and is also a potent vasodilator.

Blood transfusion

Correct anaemia. Transfuse packed red blood cells to maintain Hb>10 g/dL.

Cardiac resynchronisation therapy[37,38]

Cardiac resynchronisation has become accepted therapy in subpopulations of adults with cardiomyopathy. In children there is evidence of benefit, but patient selection is made difficult by the heterogeneous nature of the underlying diseases. Dilated cardiomyopathy may respond less well than some types of congenital heart disease.

Mechanical support[39,40]

Veno-arterial ECMO (see Ch. 41) provides excellent short-term mechanical support, but is unsuitable for the longer periods necessary for bridging to transplantation. There are very few ventricular assist devices (VADs) available for support of the smaller child. The Excor Paediatric VAD ('Berlin Heart') is the most widely used of these, with a range of ventricular chambers down to 10 mL. Successful support to transplantation or recovery can be achieved in 70–90% of cases, but there is a high risk of infective, bleeding and thrombotic complications. Larger (>30 kg) children can be supported with smaller continuous flow implantable devices designed for adults, which may carry less risk of complications. Development of miniaturised versions of these devices for children is ongoing but as yet none is ready for clinical use.

AN APPROACH TO CONGENITAL HEART DISEASE

An in-depth discussion of congenital heart disease and its management is beyond the scope of this chapter. What follows is an overview of situations in which the intensivist or emergency physician may encounter congenital heart disease, based loosely on age and mode of presentation.

NEWBORN WITH CYANOSIS[41,42]

Most cyanosed newborns have respiratory disease and this needs to be treated appropriately. Cyanosis in the absence of respiratory distress is likely to be due to congenital heart disease. Cyanotic heart disease is likely if the Pa_{O_2} does not rise to 150 mmHg (≈20 kPa) after the baby has been breathing 100% oxygen for 10 minutes. Presence or absence of a murmur is not particularly helpful; many children with cyanotic heart disease do not have a murmur and murmurs can be heard in many newborn infants. There may be diagnostic clues on examination and chest X-ray, but all such infants need an urgent echocardiogram for definitive diagnosis.

SEVERE CYANOSIS (Sa_{O_2}<70%) (SEE TABLE 108.4 FOR DRUG DOSES)

Table 108.6 shows the features of congenital heart lesions presenting with severe cyanosis at birth. These infants must be treated urgently.

1. Intubate and ventilate to reduce oxygen consumption and treat any respiratory disease. Use a high Fi_{O_2} and avoid high pressures that might increase PVR.
2. Start alprostadil (prostaglandin E_1 (PGE_1), Prostin®) to keep the ductus arteriosus open. There is a risk of exacerbating pulmonary oedema in obstructed total anomalous pulmonary venous drainage (TAPVD), but unless this diagnosis has been made with certainty the ductus should be kept open.
3. Correct metabolic acidosis.
4. Use an inotrope if there is evidence of heart failure (see above).
5. Inhaled nitric oxide may be helpful in persistent pulmonary hypertension of the newborn and severe Ebstein anomaly.
6. Refer for advice and urgent transport to a specialist paediatric cardiac centre. Persistent severe cyanosis may require ECMO support prior to definitive treatment.

LESS SEVERE CYANOSIS (<90%)

Less-profound cyanosis is seen in neonates with transposition of the great arteries (TGA) and adequate mixing, milder forms of pulmonary stenosis (including tetralogy of Fallot) and Ebstein anomaly. There is a degree of cyanosis associated with all defects where there is mixing of pulmonary and systemic venous blood (e.g. unobstructed anomalous pulmonary venous drainage, single ventricle lesions). These infants are less sick and desaturation may be relatively difficult to detect without pulse oximetry. All such children require

Table 108.6 Differential diagnosis of severe cyanosis in the newborn

LESION	PATHOPHYSIOLOGY	CHEST X-RAY	MANAGEMENT
Transposition of great arteries	Pulmonary and systemic circulations in parallel, without mixing	Normal cardiac size Narrow pedicle ('egg on side' appearance) Normal/increased pulmonary vascularity	Alprostadil Balloon atrial septostomy
Pulmonary atresia/critical pulmonary stenosis	No forward flow from right ventricle Intracardiac right to left shunting Pulmonary blood flow via ductus arteriosus	Normal cardiac size Absent pulmonary artery silhouette Reduced pulmonary vascularity	Alprostadil Will need surgery or catheter procedure
Neonatal Ebstein anomaly	Severe tricuspid regurgitation Intracardiac right to left shunting +/− pulmonary valve disease	Massive atrial enlargement Lung fields difficult to see	Alprostadil Inhaled nitric oxide May need surgical procedure
Obstructed TAPVD	Severe pulmonary venous obstruction Pulmonary oedema	Normal cardiac size Diffuse pulmonary interstitial oedema	Cardiac surgical emergency
Persistent pulmonary Hypertension of the newborn	High PVR Right heart failure Right to left shunting through ductus arteriosus	Normal cardiac size and silhouette Reduced pulmonary vascularity	Alprostadil Inhaled nitric oxide Inotropes Look for and treat underlying cause

careful assessment and prompt referral to a paediatric cardiac centre.

NEWBORN WITH CARDIAC FAILURE

In lesions that cause obstruction to the left side of the heart (aortic stenosis, coarctation, hypoplastic left heart syndrome) systemic blood flow is provided by the right ventricle through the ductus arteriosus. Patients may not present until the ductus arteriosus begins to close when systemic blood flow diminishes and the left ventricle fails in the face of greatly increased afterload. There is a rapidly deteriorating clinical picture of pallor, cold peripheries and barely palpable pulses. Tachycardia and tachypnoea are universal and there is progressive hepatomegaly, cardiomegaly and pulmonary oedema. This is accompanied by profound metabolic acidosis and oliguria.

Other conditions presenting with cardiovascular collapse in the first 2 weeks of life are sepsis, inborn errors of metabolism, myocarditis/cardiomyopathy and sustained tachyarrhythmia. These can be difficult to differentiate initially and all neonates presenting in this fashion should be treated with appropriate antibiotics (see Table 108.3) until a definitive diagnosis is made.

TREATMENT (SEE TABLE 108.4 FOR DRUG DOSES)

1. Intubate and ventilate with resuscitation drugs to hand.
2. Sedate and ventilate to reduce oxygen consumption.
3. Start inotropes – dobutamine or epinephrine depending on severity of cardiac dysfunction.
4. Start alprostadil – a high dose (50 ng/kg/min) may be needed to reopen the ductus arteriosus.
5. Refer for advice and urgent transport to a paediatric cardiac centre.

INVESTIGATIONS

- Chest X-ray
- Echocardiogram
- ECG
- Arterial blood gas, electrolytes, renal and hepatic function
- Full blood count and film examination
- Coagulation
- Blood cultures
- Serum amino acids
- Urinary amino and organic acids.

CYANOSIS BEYOND THE NEWBORN PERIOD

Infants and young children with unoperated tetralogy of Fallot may present with episodic profound cyanosis associated with crying and agitation. These 'tet spells' are mostly due to dynamic obstruction of the right ventricular outflow tract with consequent right to left shunting through the VSD. Administration of oxygen and bringing the child's knees up tight to the chest will often terminate the spell (presumably by increasing systemic vascular resistance). Volume expansion may be helpful. If there is persisting cyanosis try sedation with

morphine. In very resistant spells either a beta blocker (esmolol) or a peripheral vasoconstrictor (metaraminol) can be used. Inotropes and vasodilators will worsen the cyanosis.

Children with unrepaired or undiagnosed atrial or ventricular septal defects (or residual defects following repair) may become cyanosed under conditions of increased PVR, for example during acute respiratory illness. Cyanosis due to progressive pulmonary vascular disease with unrepaired long-standing left to right shunt (Eisenmenger's complex) is increasingly rare.

Certain operations for congenital heart disease leave patients with obligatory intracardiac mixing, producing cyanosis. Pulse oximetry in these patients will usually be in the range of 70–85% (parents will know their child's usual saturations). These children often have pulmonary blood flow supplied via an aorto-pulmonary shunt (e.g. modified Blalock Taussig ('BT') shunt or central shunt).

Two operations redirect systemic venous return directly to the pulmonary artery, bypassing the heart: the Glenn, or bidirectional cavopulmonary connection (SVC to pulmonary artery) and the Fontan (inferior vena cava (IVC) and SVC to pulmonary artery). Patients with a Glenn remain cyanosed, whereas patients with a Fontan have variable desaturation. In both cases pulmonary blood flow is extremely sensitive to PVR. If these patients require mechanical ventilation it is important to use low pressures and low rates if possible as positive intrathoracic pressure will impair pulmonary blood flow.

EMERGENCIES AND IMPORTANT PRESENTATIONS

Dehydration

Dehydration is particularly dangerous in cyanosed patients. These patients often have a high haematocrit and further haemoconcentration places them at risk of thrombosis. Intravenous rehydration should be aggressively pursued in dehydrated children with cyanotic heart disease.

Profound desaturation

Acute profound desaturation in a patient with shunt-dependent pulmonary blood flow suggests the possibility of shunt blockage and is a life-threatening emergency. Give volume (20 mL/kg 0.9% NaCl) and repeat if necessary. Discuss urgently with a paediatric cardiac centre and consider giving heparin (100 U/kg).

Intercurrent respiratory illness

Respiratory tract infections are common in childhood and these have important effects on children with limited or shunt-dependent pulmonary blood flow (see above). Increased work of breathing and increased PVR will worsen cyanosis. Respiratory failure must be treated on its merits, but the nature of pulmonary blood flow and the potential for increasing PVR must be borne in mind if mechanical ventilation is necessary.

HEART FAILURE BEYOND THE NEWBORN PERIOD[33]

Congenital-heart-disease-related heart failure beyond the newborn period is often due to the consequences of an unrepaired left to right shunt lesion. High pulmonary blood flow places a volume load on the left ventricle. Left ventricular enlargement and increased end-diastolic pressures ensue and the patient presents with tachycardia, tachypnoea, sweating, poor feeding and poor growth. There is often a gallop rhythm and a systolic murmur and peripheral vasoconstriction leads to cool peripheries. These children respond well to diuretics and ACE inhibitors, but may need inotropes and positive-pressure ventilation at presentation. Worsening cardiac failure in the first few months of life is often due to the normal fall in haematocrit at this age and will respond to blood transfusion.[43] These children will need repair of the underlying lesion, but this is rarely urgent.

An important lesion to consider in the infant with previously undiagnosed disease is anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA). These children present with poor growth and episodic inconsolable crying in the first few months of life. There is cardiomegaly and evidence of anterolateral infarction on ECG. Echo confirms markedly diminished ventricular function, ventricular dilation and mitral regurgitation. This lesion warrants rapid surgical repair.

There may be ongoing ventricular dysfunction in repaired or unrepaired congenital heart disease owing to intrinsic ventricular systolic or diastolic function, or left- or right-sided valve disease. Ischaemic cardiomyopathy occurs rarely but can be seen following repair of coronary artery abnormalities or operations involving manipulation or reimplantation of the coronaries, most notably the arterial switch operation.[44]

EMERGENCIES AND IMPORTANT PRESENTATIONS

Intercurrent respiratory illness

Respiratory tract infections will cause an exacerbation of heart failure in children with congenital heart disease. Increased work of breathing and fever are poorly tolerated and often necessitate hospitalisation. This is most commonly seen in infants with unrepaired left to right shunt lesions and viral respiratory tract infections during the winter. It may be difficult to differentiate the effects of the respiratory disease from the heart failure, but initial attention to treatment of respiratory failure must be accompanied by careful assessment of the underlying disease.

DISORDERS OF CARDIAC RHYTHM (SEE FOR DRUG DOSES)

SINUS BRADYCARDIA

Sinus bradycardia (see Table 108.2) may appear more dramatic due to the frequent occurrence of sinus

arrhythmia in children. Pathological causes of bradycardia include sinus node dysfunction, hypothermia, high intracranial pressure, cervical spinal cord injury, hypothyroidism, drug effects (beta blockers, digoxin, amiodarone, clonidine) and organophosphate poisoning. Sinus bradycardia very rarely needs treatment apart from addressing any underlying cause. Atropine or isoproterenol (isoprenaline) will increase the heart rate if necessary (Table 108.4).

SINUS NODE DYSFUNCTION

Sinus node dysfunction causes bradycardia, sinus pauses, and alternating bradycardia/tachycardia. It is most common following operations for congenital heart disease, particularly those involving extensive atrial surgery, and can occur many years later. Sinus node dysfunction is rare in children with structurally normal hearts and is well tolerated in this group. Emergency treatment involves treatment of bradycardia, if symptomatic, and consideration for pacemaker insertion.

COMPLETE HEART BLOCK

Complete heart block is usually congenital in children, with more than 90% being due to transplacental passage of maternal autoantibodies in autoimmune disease. In later childhood complete heart block is most likely to be associated with recent cardiac surgery or complex forms of congenital heart disease (congenitally corrected TGA, left atrial isomerism), but may also occur with myocarditis, cardiomyopathy, cardiac transplant rejection and some muscular dystrophies.

MANAGEMENT

Atropine will increase the ventricular rate and an infusion of isoproterenol will maintain it pending establishment of temporary or permanent cardiac pacing.

Inotropes should be used in patients with poor ventricular function due to long-standing bradycardia or underlying myocardial disease.

Transvenous temporary pacing is difficult in small children and external cardiac pacing may be necessary as a resuscitative measure.

Asymptomatic patients may still require insertion of a pacemaker, depending on cause, ventricular escape rate and myocardial function.

FIRST-DEGREE HEART BLOCK

A prolonged PR interval (see **Table 108.7**) can be seen in normal children during periods of increased vagal tone. Pathological causes of first-degree block include hypothermia, electrolyte abnormalities, acute rheumatic fever and any of the causes of complete heart block described above.

SECOND-DEGREE HEART BLOCK

Isolated Mobitz type I block (Wenckebach) is usually well tolerated. Mobitz type II is more likely to be symptomatic and require a pacemaker. Either form of second-degree AV block should be investigated for an underlying cause.

TACHYARRHYTHMIAS

Sinus tachycardia (see Table 108.2) is more common than tachyarrhythmia. Underlying causes (fever, pain or agitation, drugs) should be considered and treated.

SUPRAVENTRICULAR TACHYCARDIA (SVT) (SEE CH. 21)

Re-entrant SVT is common in childhood. Most cases occur in the first few months of life in the absence of congenital heart disease. Structural heart disease should be ruled out in all cases, however.

The re-entry circuit usually involves the atrioventricular (AV) node and an accessory conduction pathway. These tachycardias are abrupt in onset and have a relatively fixed rate. In neonates and infants the accessory pathway is discrete from the AV node and may conduct in either direction (accessory-pathway-mediated SVT). In older children and adults the alternative conduction route is often within the AV node itself, with two limbs of the node conducting at different frequencies and with different refractory periods (AV node re-entrant tachycardia).

Diagnosis

The ECG shows a narrow complex (see Table 108.7) tachycardia at greater than 200 beats per minute. P-waves are often difficult to discern, but occur with a 1:1 ratio to the QRS complexes. P-waves are usually inverted, but morphology and position will depend on the nature of the re-entry circuit.

Treatment

If shocked give:

- oxygen by mask, and sedation (midazolam)
- synchronised DC cardioversion (1 J/kg).

Table 108.7 Age-related approximate ECG intervals (and upper limits of normal)[49]

	NEWBORN	6–12 MONTHS	5–8 YEARS	12–16 YEARS
PR interval (ms)	100 (120)	110 (140)	130 (160)	135 (180)
QRS duration (ms)	65 (85)	65 (85)	80 (100)	90 (110)
QTc interval (ms)	420 (450)	410 (450)	410 (445)	410 (450)

All intervals in milliseconds. QTc= corrected QT interval=QT$\sqrt{}$(heart rate/60).

If stable:

1. *Vagal stimulation:* apply ice water to entire face for <30 seconds, gag, tracheal suction or held inspiration if ventilated. Give carotid sinus massage in older children. Do not apply eyeball pressure.
2. *Adenosine rapid i.v. bolus and flush:* give as centrally as possible. If unresponsive increase the dose (see Table 108.4). Adenosine is painful and causes vasodilatation.
3. *Atrial or transoesophageal overdrive pacing:* may terminate the arrhythmia.
4. *If unsuccessful or the tachycardia reverts after successful termination:* consider amiodarone or digoxin.
5. Do *not* use digoxin or verapamil if there is pre-excitation on the ECG (they both may enhance anterograde conduction in the accessory pathway).
6. Do *not* use verapamil in infants (it can cause shock and cardiac arrest).
7. *Following conversion to sinus rhythm:* check ECG for evidence of pre-excitation and look for structural disease.

Automatic SVTs are caused by an 'ectopic' rapidly firing focus within the atrium or AV conducting tissue. These are unusual in the absence of structural heart disease and are commonly seen following cardiac surgery. Typically there is variability of ventricular rate.

Ectopic atrial tachycardia (EAT) has an abnormal P-wave axis on the ECG with normal conduction to ventricles. Junctional ectopic tachycardia (JET) arises at the AV node or high in the bundle of His. There is complete AV dissociation on the ECG, the ventricular rate being greater than the atrial rate.

Treatment is aimed at reducing automaticity with adequate sedation and analgesia, and avoiding catecholamines and other chronotropes. Keep serum potassium, calcium and magnesium in the high normal range. Whole-body cooling is useful. Amiodarone can be used in resistant postoperative JET.

Atrial fibrillation

Atrial fibrillation is rare in children and is usually associated with cardiomyopathy or previous atrial surgery.

Box 108.2 Causes of ventricular arrhythmias in children

Congenital heart disease (repaired tetralogy of Fallot, aortic stenosis)
Cardiomyopathy
Myocarditis
Ischaemia (coronary abnormalities, Kawasaki disease)
Transplant rejection
Electrolyte abnormalities (hypo/hyperkalaemia, hypocalcaemia)
Drugs (tricyclic antidepressants)
Cardiac channelopathies (long QT syndrome, Brugada syndrome)
Cardiac tumours
Commotio cordis

Atrial flutter

Atrial flutter is an atrial re-entrant tachycardia. It can occur in newborns in the absence of structural heart disease but is more common in older patients with congenital heart disease, particularly those who have had surgery involving extensive atrial manipulation. Atrial flutter rates in children are faster than adults (>400 per minute in newborns). Diagnosis may be evident from the sawtooth baseline pattern of the ECG, but this may not be revealed until adenosine is given, blocking AV conduction.

Treat shocked patients as described above for SVT.

In the stable patient, atrial or transoesophageal overdrive pacing may terminate the arrhythmia.

VENTRICULAR ARRHYTHMIAS

Isolated premature ventricular contractions are common in infants and children with normal hearts. Ventricular arrhythmias are very rare in children (most cases of paediatric cardiac arrest present with severe bradycardia or asystole). Documented ventricular fibrillation or ventricular tachycardia must prompt an exhaustive search for an underlying cause (**Box 108.2**).

Emergency treatment of ventricular arrhythmias is described in Chapter 113.

Neurological emergencies in children

Anthony J Slater

Neurological emergencies are the most common life-threatening emergencies in children. In developed societies, after the first year of life, the leading cause of death in childhood is injury, particularly traumatic brain injury. There is a range of conditions affecting the brain, spinal cord and peripheral nervous system that require prompt recognition, resuscitation and definitive management. The pathophysiology, clinical features, treatment and outcome of these acute neurological emergencies are influenced by several important differences between adults and children. These differences include response to injury, developmental maturity and capacity for growth and recovery.

PATHOPHYSIOLOGY OF BRAIN INJURIES IN CHILDREN

Brain injuries are usually caused by a primary event (e.g. trauma, ischaemia, infection or metabolic disturbance) and are frequently accompanied by secondary injuries including oedema, altered cerebrovascular autoregulation, tissue hypoxia or other cytotoxic events. Therapy administered after the event will not influence the outcome of the primary injury, however, appropriate resuscitation, treatment and the avoidance of iatrogenic complications may prevent or reduce the impact of secondary injuries.

Features of brain injury particular to the paediatric patient are described below.

DIFFUSE CEREBRAL SWELLING

Diffuse brain swelling in the absence of oedema is a frequent early finding in paediatric brain injury, and is due to generalised cerebral vasodilation. It often resolves in 1–2 days if there is no other significant brain injury. With more severe primary traumatic injury diffuse cerebral swelling may be accompanied by areas of contusion, multifocal petechial haemorrhage, and vasogenic oedema that progress over several days.

CEREBRAL BLOOD FLOW AND METABOLISM

The cerebral perfusion pressure (CPP) represents the difference between mean arterial pressure (MAP) and intracranial pressure (ICP):

$$CPP = MAP - ICP$$

If autoregulation is disturbed as part of the illness, CPP becomes the major determinant of cerebral blood flow, particularly in areas with more severe damage. The ideal CPP in childhood is not known. The normal range of MAP varies with age from 40 mmHg (5.32 kPa) in a term neonate to 80 mmHg (10.64 kPa) in an adolescent. The target CPP is usually adjusted with age, taking into consideration the normal blood pressure for age. For example, for an adolescent patient the therapy may be directed at maintaining a CPP of 60 mmHg (7.98 kPa), whereas for a child aged 5 years the aim may be to maintain a CPP of 50 mmHg (6.65 kPa).

In conditions where vasogenic oedema occurs, arterial hypertension may increase vascular shift of fluid and worsen brain swelling. However, treatment aimed at lowering arterial pressure (e.g. with vasodilators) may interfere with homeostatic mechanisms and should be used cautiously.

The brain comprises 12% of body weight in infancy compared with 2–3% in adulthood. Cerebral oxygen and glucose consumption are therefore proportionately greater in childhood and glycogen stores are readily depleted. Hypoglycaemia occurs commonly in severe illnesses such as sepsis; therefore blood glucose should be monitored regularly.

HYPOVOLAEMIA

Children have small blood volumes and commonly develop hypovolaemia from scalp bleeding or intracranial haemorrhage. For example, hypovolaemia will develop in a 5 kg infant (blood volume 400 mL) following blood loss of less than 100 mL. Hypovolaemia should be treated aggressively with fluid boluses of 20 mL/kg to ensure adequate cerebral perfusion.

RELATIVE GROWTH

The child's short stature and proportionately large head confer a number of risks. The toddler's head is at the level of the front of a motor vehicle and isolated head injury is therefore common following pedestrian injury in this age group. The neck muscles are relatively weak in infancy and they support a large head. This renders the brain prone to deceleration injury in motor vehicle crashes and in cases of domestic violence. Injury

inflicted by shaking an infant by the shoulders snaps the head to and fro leading to compression of brain tissue and rupture of delicate bridging veins.

BONE DEVELOPMENT

The skull bones in the first year of life are thin with open sutures and open fontanelles. Beyond 2 years, the skull sutures close and the cranial vault thickens. In young children there tends to be less bony protection from high-impact trauma, although the non-rigid skull may expand to partially decompress expanding lesions.[1]

UNDIAGNOSED COMA

An ordered approach to diagnosis and treatment is required for a child with depressed conscious state of unknown origin. This approach must consider common life-threatening and rare treatable diseases (**Box 109.1**).

INITIAL MANAGEMENT

Management should always begin with rapid assessment of the adequacy of airway, ventilation and circulation. If inadequacies are detected, interventions aimed at correcting them should occur immediately. Once venous access is obtained, blood should be collected for routine tests including immediate measurement of blood glucose. If hypoglycaemia is demonstrated 1–2 mL/kg of 25% glucose or 2.5–5 mL/kg of 10% glucose should be given intravenously as the neurological sequelae of unrecognised hypoglycaemia can be profound.

Box 109.1 Causes of trauma in children

Structural	Metabolic
Trauma	Post-ictal state
Accidental	Infection
Inflicted	Meningitis
Hydrocephalus	Encephalitis
Haemorrhage	Acute disseminated encephalomyelitis
AVM	Drugs and toxins
Aneurysm	Hypoxia–ischaemia
Tumour	Circulatory shock
Tumour	Biochemical
Cerebral abscess	Hypoglycaemia
	Sodium and/or water disorder
	Calcium disorder
	Acid–base disorder
	Hyperthermia
	Hepatic failure
	Haemolytic–uraemic syndrome
	Inborn errors of metabolism

Concurrent with the initial assessment and resuscitation, relevant details of the present and past history should be obtained. A detailed neurological and general physical examination should be performed. It is important to document accurately the conscious state so that changes over time, particularly deterioration, can be easily recognised. The Glasgow Coma Scale (GCS) is appropriate for this purpose; the responses of children change with development and therefore the GCS requires modification for paediatric use (**Table 109.1**). After completing the clinical assessment, the likely diagnosis is often apparent and appropriate investigation and treatment can commence. Multiple factors may compound to produce coma. For example, a child with severe gastroenteritis may have hyperthermia, hyponatraemic dehydration, metabolic acidosis and hypovolaemic shock.

CONTROLLED VENTILATION

Indications for ventilating a comatose child are:

- upper airway obstruction or loss of airway reflexes
- apnoea or respiratory failure
- rapidly worsening coma
- signs of progressive elevation of ICP (i.e. bradycardia, hypertension, abnormal pupillary light reflexes and localising signs).

Once ventilation is initiated the stomach should be drained with a gastric tube and blood pressure checked every 5 minutes. Raised ICP should be considered in any case of rapidly progressive coma. If critical intracranial hypertension is suspected clinically, management should include moderate hyperventilation and intravenous mannitol (0.25 g/kg). Hypertonic saline given as 3 mL/kg of 3% solution (0.5 mmol/mL) can also rapidly reduce ICP.[2] Once stability is achieved then adequate sedation and analgesia are required. Muscle relaxants may be necessary to facilitate ventilation and prevent straining; however, their use precludes further neurological assessment and therefore, if long-acting muscle relaxants are continued, ICP monitoring is advisable. Hyperventilation is a short-term manoeuvre and, if used during the early resuscitation phase, a gradual return to a low–normal Pa_{CO_2} should be the aim. This is best achieved with end-tidal CO_2 and ICP monitoring. Particular attention should be paid to restoring intravascular volume and maintaining an adequate CPP.

CRANIAL COMPUTERISED TOMOGRAPHY

A CT scan is required in comatose children with localising signs and in those in whom the diagnosis is not clear. A CT should also be performed if the conscious state is abnormal and there is history of trauma. Even if the general condition doesn't warrant controlled ventilation, a CT is often best performed under general

Table 109.1 Glasgow Coma Scale for children

GLASGOW COMA SCALE (4–15 YEARS)		CHILD'S GLASGOW COMA SCALE (<4 YEARS)	
RESPONSE	*SCORE*	*RESPONSE*	*SCORE*
EYE OPENING		EYE OPENING	
Spontaneously	4	Spontaneously	4
To verbal stimuli	3	To verbal stimuli	3
To pain	2	To pain	2
No response to pain	1	No response to pain	1

Inappropriate words	3	Cries only to pain	3
Incomprehensible sounds	2	Moans to pain	2
No response to pain	1	No response to pain	1

anaesthesia. Unwanted movement will cause poor-quality images and sedation alone may place the child at risk of hypoventilation or aspiration.

LUMBAR PUNCTURE

Lumbar puncture (LP) should be performed when there is reasonable suspicion of meningitis or encephalitis. The risks and contraindications to LP are discussed under bacterial meningitis.

ADDITIONAL INVESTIGATIONS

Additional investigations include arterial blood gas analysis, serum electrolytes, glucose, urea and creatinine, liver function tests, serum ammonia, serum and CSF lactate and pyruvate and urine analysis. Appropriate screening of blood and urine will exclude common poisons and drug intoxications.

SPECIFIC TREATMENT

The clinical signs and results of investigations generally guide treatment. If hypoglycaemia occurs, it should be corrected rapidly and care should be taken to ensure that it does not recur by the administration of appropriate glucose-containing i.v. fluid and regular blood glucose monitoring. Herpes simplex encephalitis can present in many ways and is not excluded by the absence of CSF pleocytosis. Acyclovir therapy should therefore be considered in any patient in whom herpes cannot be confidently excluded.

STATUS EPILEPTICUS

Convulsive status epilepticus (CSE) is usually defined as a continuous convulsion lasting 30 minutes or longer or repeated convulsions lasting 30 minutes or longer without recovery of consciousness between convulsions.[3] As 30 minutes is generally considered too long to wait before starting treatment, an alternative 'operational definition' of a seizure lasting more than 5 minutes has been proposed for adults and older children (>5 years old). It is acknowledged that the biology and clinical features of CSE in young children differ from that in adults.[4] The common causes of CSE in children are:

- prolonged febrile convulsion
- epilepsy associated with the first presentation, anticonvulsant withdrawal or intercurrent illness
- central nervous system infection (e.g. meningitis or encephalitis)
- metabolic disturbance (e.g. hypoglycaemia, hyponatraemia, hypocalcaemia)
- trauma, including inflicted injury.

PATHOPHYSIOLOGY

Many physiological changes occur during prolonged seizures. There is an initial phase of compensation lasting less than 30 minutes. Following a period of transition there is a phase of decompensation commencing between 30 and 60 minutes and evolving over hours. Physiological changes during the compensated phase

include tachycardia, hypertension, increased catecholamine release and increased cardiac output. Changes within the brain include increased cerebral blood flow and increased cerebral utilisation of glucose and oxygen. After 30–60 minutes the mechanisms for homeostatic compensation fail. During the decompensated phase there may be falling blood pressure and cardiac output, hypoglycaemia, hypoxia, acidosis, electrolyte disturbance, and rhabdomyolysis. The cerebral physiology is characterised by failing autoregulation and reduced cerebral blood flow and oxygen and glucose utilisation. Over hours a deficit in brain energy develops and this is associated with the development of brain damage.[5]

EXCITATORY AMINO ACIDS AND BRAIN INJURY

Mesial temporal sclerosis is the most common acquired brain lesion following CSE. There is evidence that the accumulation of a number of excitatory and inhibitory amino acids has a role in the pathophysiology of neuronal injury. In particular, glutamate accumulation and stimulation of NMDA receptors lead to an influx of intracellular calcium, which triggers a number of cytotoxic events and ultimately cell death.[6]

MANAGEMENT

The initial management is as for other neurological emergencies with attention to airway and oxygenation. Most seizures in childhood cease spontaneously in a short time, but if they persist after presentation to an emergency department they should be stopped to avoid metabolic and ischaemic neuronal damage. Hypoglycaemia should be excluded or detected early.

FIRST-LINE THERAPY

Benzodiazepines remain the first-line antiepileptic drug (AED) for stopping seizures and should be administered for seizures that do not stop spontaneously within 5 minutes. The efficacy of benzodiazepines is reduced if administration is delayed.[7] Therefore there is strong argument for first-line therapy to be administered prehospital either by the parents, care providers, or paramedics.[8] Intravenous access is unlikely in the community; however, midazolam can be administered via the buccal, intranasal, or intramuscular route. Buccal midazolam is more effective, easier and more socially acceptable to administer then rectal diazepam.[9–11] Once intravenous access is available lorazepam is usually considered the drug of choice as, compared with diazepam, it is at least as effective, safer and has a longer duration of action.[12–14] If a seizure has not responded to two doses of benzodiazepine, a second-line AED should be administered. If a benzodiazepine has been administered pre-hospital then only one further dose should be administered in the emergency department.

SECOND-LINE THERAPY

Phenytoin is the second-line AED of choice in most situations. It is given as 20 mg/kg i.v. over 30 minutes, which is followed by maintenance dosing (4–8 mg/kg/day in 2-3 doses). It causes minimal sedation or respiratory depression, but is not suitable in neonates and in patients who are already on maintenance doses. Fosphenytoin, a prodrug of phenytoin, can be administered intramuscularly and has less irritant effect when given i.v.[15] Its place in the management of CSE in children is not yet clear. When phenytoin is contraindicated, phenobarbitone (20 mg/kg i.v. over 30 minutes) should be given. Respiratory depression and hypotension occur, particularly after benzodiazepines. Further doses can be safely administered to ventilated children who have ongoing seizures.

THIRD-LINE THERAPY

Levetiracetam is effective against a broad range of seizure types and can be administered enterally or intravenously. Case series have described the use of intravenous levetiracetam (20–60 mg/kg over 5–15 minutes) in children with CSE. These reports suggest that the drug is safe and effective either as a single agent or in combination with other AEDs.[16] Valproate is commonly used for maintenance therapy in epilepsy. There are several reports of successfully using intravenous valproate to abort CSE in children. The doses reported range from 20 to 40 mg/kg. The rate of infusion reported also varies from 5 to 30 minutes.[17] Valproate can rarely cause encephalopathy or hepatotoxicity. Therefore levetiracetam may have a safety advantage over valproate as a third-line agent for CSE. In many centres rectal paraldehyde (0.3 mL/kg, max 5 mL, mixed with an equal quantity of olive oil) is frequently used in the management of CSE. One advantage of paraldehyde is that, like diazepam, it can be administered rectally if i.v. access is difficult to obtain.

FOURTH-LINE THERAPY

If CSE continues for longer than 30–60 minutes despite the administration of two or at most three different AEDs, induction of intravenous anaesthesia should occur followed by intubation and ventilation and admission to intensive care. Thiopentone 2–5 mg/kg slowly i.v. then 1–5 mg/kg per hour by continuous infusion into a central vein can be given. Thiopentone necessitates endotracheal intubation and mechanical ventilation, and possibly inotropic drugs to counter its myocardial depressant effects. Blood concentrations need to be monitored during prolonged use. Seizures are only controlled by anaesthetic doses of thiopentone. Midazolam infusion has been used as an alternative to thiopentone. After a bolus of 0.2 mg/kg (maximum 10 mg) an infusion is commenced at 0.1 mg/kg per hour. If seizures continue or recur the bolus dose is repeated and the infusion increased up to 1 mg/kg per hour if tolerated, although even higher doses have been reported.[18–20] When muscle relaxants are used to facilitate intubation, they should be short-acting to ensure ongoing seizure activity is not masked.

The patient must be protected from self-injury during seizures. Severe respiratory and metabolic acidosis are common and are best managed by rapid control of the seizure and maintenance of adequate ventilation and oxygenation. Once seizures are controlled, the cause should be sought. A detailed history is invaluable. A CT scan should reveal structural lesions. An LP should be deferred if the child is unconscious after a seizure. However, if the conscious state improves and there are no signs of raised intracranial pressure (see below) an LP will confirm or exclude meningitis. When the diagnosis remains unclear, viral encephalitis (e.g. herpes simplex or enterovirus), metabolic encephalopathy, poisoning and inflicted injury should be considered.

OUTCOME

The outcome of CSE is dependent on the aetiology. Neurologically normal children in whom CSE is precipitated by fever are considered to have a good prognosis with mortality reported between 0 and 2%.[21] The incidence of neurological deficits or cognitive impairment in this group is also very low. In acute symptomatic CSE (where CSE is a symptom of an acute neurological process such as infection, or trauma) mortality is 12–16% and the incidence of new neurological dysfunction is more than 20%.[21] In this setting, however, it is very difficult to tease out the extent to which prolonged seizures contribute to neurological sequelae.

BACTERIAL MENINGITIS

PATHOPHYSIOLOGY

Bacterial meningitis (BM) usually occurs following haematogenous spread of organisms carried in the nasopharynx. In childhood the common bacteria causing BM are *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae* type b (Hib). Group B *Streptococcus*, *Escherichia coli* and *Listeria monocytogenes* are the most common causative organisms of neonatal BM. Occasionally, meningitis occurs as a complication of other pathology such as base of skull fracture, chronic middle ear infection, or infection of a congenital dermoid sinus.

In the early stages of the disease cerebral hyperaemia occurs. This can be followed by cerebral ischaemia, which may occur by several different mechanisms. Local vasculitis of vessels traversing the subarachnoid space can progress to arterial thrombosis and focal infarction. Other vascular abnormalities including vasospasm and sagittal sinus thrombosis can also occur. Cerebral oedema is relatively common in meningitis and is caused by a combination of vasogenic, cytotoxic and hydrostatic factors. If cerebral oedema is severe then raised ICP and impaired cerebral perfusion can occur leading to global cerebral ischaemia.

CLINICAL FEATURES

In children the typical features of BM are fever, headache, photophobia, neck stiffness and vomiting. The history may extend over several days; however, in fulminant cases the time from first symptom to coma and death may only be a few hours. Neonates and young infants do not present with the typical localised symptoms and signs. Instead, they present with generalised signs of illness including lethargy, poor feeding and pallor. Generalised or focal convulsions or apnoea may be present at presentation. Tuberculous meningitis usually presents with a more insidious onset of symptoms and may be associated with focal neurological signs.

Complications occur commonly in BM. During the early phase, meningitis may be associated with septic shock and disseminated intravascular coagulation (DIC). Fluid and electrolyte abnormalities are relatively common, particularly hyponatraemia and hypoglycaemia. Focal and generalised convulsions are also relatively common and may progress to status epilepticus. During the recovery phase subdural effusions or hydrocephalus may occur.

INVESTIGATIONS

Lumbar puncture (LP) for CSF microscopy, culture and polymerase chain reaction (PCR) testing is required for definitive diagnosis of BM and to guide antibiotic therapy. Although a lumbar puncture can be performed safely in the majority of children with BM, LP may precipitate brainstem herniation if raised intracranial pressure (ICP) is present.[22] Identifying children at risk of this complication is difficult; however, it is generally recommended that empirical antibiotic therapy be commenced and LP deferred if any of the following clinical features are present: depressed conscious state, decorticate or decerebrate posturing, focal neurological signs or other signs of raised ICP. A normal CT scan does not exclude the possibility of elevated ICP.[22] Therefore the decision to defer an LP should be based on clinical rather than radiological signs. In addition to signs of increased intracranial pressure, other indications for deferring the LP include cardiorespiratory instability and severe coagulopathy.

If LP is deferred then alternative methods of establishing a bacterial diagnosis include blood culture and bacterial antigen testing in urine and PCR testing of blood.[23,24]

MANAGEMENT

RESUSCITATION

Severely ill patients require rapid resuscitation. Comatose patients require intubation and ventilation to prevent airway obstruction and hypoventilation. Hypovolaemia should be treated rapidly with boluses of

fluid. Patients with septic shock will also require inotropic support.

Cerebral resuscitation

General principles of supporting brain injury apply to BM. These include optimising cerebral oxygen delivery, controlling intracranial pressure and preventing cerebral metabolic stress. The role of ICP monitoring is controversial. There is some anecdotal evidence to support the use of ICP monitoring in a small number of selected cases. Unfortunately, there are no large studies that assess the benefit or harm of ICP monitoring and ICP-targeted therapy in BM.

ANTIBIOTIC THERAPY

Empirical broad-spectrum antibiotics should be selected based on likely pathogens and local resistance patterns. A common protocol for BM is to use ampicillin plus cefotaxime for the 3 months of life and to use a third-generation cephalosporin (cefotaxime or ceftriaxone) after the first month.[25–26] In regions where penicillin- and cephalosporin-resistant *Pneumococcus* occurs, vancomycin should be added to the initial empirical antibiotics until the causative organism is identified and the antibiotic sensitivities are known. When cephalosporin-resistant *Pneumococcus* are found to be the causative organism in meningitis, both a third-generation cephalosporin and vancomycin should be continued as vancomycin penetrates into CSF poorly and therefore should not be used as a single agent. The addition of rifampicin should be considered.[27]

ADJUVANT THERAPY

If dexamethasone is used as adjuvant therapy it should be used only for children over 3 months of age and ideally be given before the first dose of antibiotics and continued for 48 hours (0.4 mg/kg 12-hourly).[28] There is evidence that dexamethasone reduces the incidence of neurological sequelae and sensorineural deafness; however, the beneficial effects are greatest in Hib meningitis (*Haemophilus influenzae*).[29,30] With immunisation, changing epidemiology and the emergence of antibiotic-resistant pneumococcal strains, it is possible that the relationship between risk and benefit of dexamethasone therapy has changed. However, current recommendations support the use of dexamethasone for children greater than 3 months of age with bacterial meningitis.[26,27,31] Oral glycerol also has promise as an adjuvant agent. One recent large randomised controlled trial demonstrated that oral glycerol administration, with or without dexamethasone, was associated with reduced neurological sequelae compared with placebo.[32]

FLUID THERAPY

There is consensus that hypovolaemia should be treated rapidly and aggressively; however, fluid therapy after the initial resuscitation is controversial. It is important to consider the tonicity of i.v. fluids as well as the rate of fluid administration. Hypotonic fluids should not be administered in BM owing to the risk of hyponatraemia and cerebral oedema.[33,34] Hyponatraemia is often attributed to the syndrome of inappropriate antidiuretic hormone secretion and therefore fluid restriction is logical. There is evidence, however, that ADH is *appropriately* elevated in response to hypovolaemia[35] and that hyponatraemic patients with BM tend to be more dehydrated than normonatraemic patients.[36] Compared with fluid restriction, fluid therapy aimed at providing maintenance plus correcting the fluid deficit has been reported to result in a more rapid correction of sodium and ADH[35,37] and has also been associated with reduced short-term morbidity and neurological sequelae at follow-up.[38] The trials of fluid therapy in BM have all been undertaken in low-income countries where delayed presentation is common. The effect of fluid therapy on the outcome of BM in populations where children present early and mortality is low is unknown.

OUTCOME

Bacterial meningitis is associated with significant mortality and morbidity. Overall mortality for BM in childhood is 5–10%; however, in children requiring mechanical ventilation, a mortality rate of 30% has been reported with major neurological sequelae occurring in 33% of survivors.[39]

ENCEPHALITIS

Common causes of encephalitis include enteroviruses, mycoplasma, cytomegalovirus, herpes, Epstein–Barr and respiratory viruses (adenovirus and parainfluenzae). The most significant causes worldwide are the insect-transmitted arbovirus encephalitides including Australian (Ross and Murray Valley), Japanese B and St Louis. These can cause profound coma and are associated with significant incidence of residual neurological deficit.

Presenting symptoms of encephalitis include seizures, focal neurological deficits in the setting of an acute febrile illness, confusion and coma. Meningeal irritation may not be obvious. CSF analysis may show a pleocytosis and in the early phase this can consist predominantly of neutrophils. As mentioned, herpes is the most important diagnosis to make, because it is treatable. Electroencephalography (EEG), CT and magnetic resonance imaging (MRI) are helpful in making the diagnosis. MRI is more sensitive than CT for detecting signs of encephalitis, particularly during the early stages of the illness. PCR on CSF may also aid rapid diagnosis.[40,41] Acyclovir if used early improves outcome and should be commenced when the diagnosis is suspected.

The enteroviruses are important causes of encephalitis in children. In addition they cause other acute neurological illnesses including acute flaccid paralysis due to transverse myelitis and Guillain–Barré syndrome.[42] Pleconaril is a promising new antiviral agent that

appears to have clinical benefit in enteroviral infections, including CNS disease.[43] Outcome of viral encephalitis is worse in infancy than in older age groups.[44]

NON-TRAUMATIC INTRACRANIAL HAEMORRHAGE

Non-traumatic intracranial haemorrhage (ICH) is uncommon in children. Arteriovenous malformations (AVM) are a more common cause of haemorrhage in children than aneurysms[45] (**Box 109.2**). The presenting features are similar to those seen in adults, and include sudden severe headache, altered conscious state and seizures. Diagnosis can usually be made by CT scan. Raised ICP, if present, is managed in the usual manner. A mass lesion or acute obstructive hydrocephalus requires neurosurgical assessment. Following diagnosis of ICH, further investigations may be required to clarify the underlying cause. These include coagulation profile and platelet count. Angiographic images can be obtained with CT, magnetic resonance (MRA) or digital subtraction. In some cases definitive cerebral angiography may be required to define the underlying vascular malformation or tumour. Definitive surgery or endovascular treatment of an AVM can be planned once the underlying lesion has been defined. A period of close observation is required as children may be at greater risk of rebleeding from an AVM than adults. The efficacy of therapies (e.g. calcium channel blockers) used to prevent vasospasm in adults has not been studied in children with aneurysmal haemorrhage. Sequelae of ICH include hemiparesis, aphasia, seizures and hydrocephalus.

HYPOXIC–ISCHAEMIC ENCEPHALOPATHY AETIOLOGY

The most common causes of hypoxic–ischaemic encephalopathy outside the neonatal period are:

- near-miss sudden infant death syndrome
- immersion
- accidents, including drug ingestion and strangulation
- inflicted injury.

PATHOLOGY

The brain depends on an uninterrupted supply of oxygen and glucose to produce, via aerobic glycolysis, sufficient high-energy adenosine triphosphate (ATP) to maintain neuronal membrane and synthetic function. Under anoxic conditions anaerobic glycolysis occurs, which produces lactic acid but less ATP (by 18 times). As there are virtually no stores of ATP, rapid neuronal failure ensues. If ischaemia accompanies hypoxia, there is associated failure of both substrate delivery and metabolic waste removal, which amplifies the cellular insult. Ischaemia produces coma in less than 10 seconds and cerebral damage in as little as 2 minutes.

Following restoration of cerebral blood flow there is a period of relative hyperaemia followed by relative hypoperfusion. Cytotoxic cerebral oedema may subsequently develop, but significant elevation of ICP is unusual unless ischaemia and damage are profound.

MANAGEMENT

The principles of therapy are similar to those for other brain injuries. It is mandatory to provide rapid cardiopulmonary resuscitation and prevent secondary insults. In cases of out-of-hospital cardiac arrest, full resuscitation must be attempted while the history is sought. Post-resuscitation care is important for optimising outcome. Comatose patients with hyper- or hypotonia and a Glasgow Coma Scale (GCS) score <8 are probably best managed by mechanical ventilation and sedation for at least 1–2 days, although benefits are not proven. Ventilation should be targeted at normocapnoea, and hyperventilation avoided owing to the risk of further cerebral ischaemia.[46] Haemodynamic disturbance may develop because of primary cardiac dysfunction or hypovolaemia secondary to fluid loss from capillary leak syndrome. Circulating volume should be restored and inotropic agents considered so as to improve the state of the circulation. The dose and choice of vasoactive agent should be individualised based on haemodynamic monitoring.

Following cardiac arrest children are usually hypothermic. Fever commonly develops during the subsequent hours and is associated with worse outcome.[47] Therefore fever should be anticipated and prevented. Further to preventing fever, there is evidence that therapeutic hypothermia of 32–34°C improves outcome. There are trials in adults following cardiac arrest[48,49] and trials in newborns following birth asphyxia[50,51] demonstrating improved neurological outcome if hypothermia is used for between 12 and 72 hours. Although

there are no paediatric trials, therapeutic hypothermia should be considered as a treatment option in children who are comatose following hypoxic ischaemic events. Hyperglycaemia has been associated with a worse prognosis and, although it may simply be a marker of injury severity, active treatment has been advocated. The role of ICP measurement is limited as intracranial hypertension usually occurs only in the setting of severe injury and poor outcome.[52]

PROGNOSIS

The major determinants of recovery are ischaemic time, cerebral metabolic rate and quality of resuscitation. In immersion injuries in young children, full recovery may be possible despite prolonged ischaemia if sufficient rapid cerebral cooling has occurred. In these cases the onset of ischaemia may be delayed by bradycardia with preferential cerebral flow (the 'diving reflex'). In general, survival from out-of-hospital cardiac arrest is unlikely, even with expert CPR, if asystole is present on arrival at hospital.[53] The rare exception is the hypothermic child who presents following immersion; prolonged CPR may be justified in selected cases when profound hypothermia was induced rapidly. If cardiac output is present on arrival at hospital, with either flexion or extension to pain, recovery is likely. Normothermic patients, who present apnoeic, flaccid and unresponsive to pain, are likely to die or have serious neurological deficits. This group is also prone to further deterioration several days after the insult, with progression of cerebral oedema. Coma persisting for more than 24 hours is a predictor of poor prognosis and minimal long-term improvement is likely in this group.[54] Residual neurological deficits present at the end of the first week are less likely to improve following ischaemic injury than following traumatic brain injury.

A number of ancillary tests have been investigated as predictors of neurological outcome. Somatosensory evoked potentials (SEPs) performed at the bedside are the most useful aid to prediction. One report of 109 children with severe brain injury concluded that, with appropriate patient selection, the positive predictive value for poor outcome of bilaterally absent SEPs is 100% (95% CI 92–100%).[55]

GUILLAIN–BARRÉ SYNDROME

CLINICAL FEATURES

Guillain–Barré syndrome (GBS) is characterised by acute areflexic paralysis with raised CSF protein and normal CSF cell counts. It is the most common cause of acute motor paralysis in children. There is strong evidence to support an autoimmune cause with many patients having raised anti-ganglioside antibodies. Many cases are preceded by symptoms of upper respiratory tract infection or diarrhoea. Infectious agents associated with subsequent development of GBS include *Campylobacter jejuni*, cytomegalovirus, Epstein–Barr virus, varicella zoster virus and *Mycoplasma pneumoniae*. The syndrome includes a number of peripheral nerve disorders that have been classified based on the distribution of weakness, antibody profiles and nerve conduction studies.[56]

Although most patients develop typical ascending, symmetrical areflexic weakness, GBS may present insidiously with apparent lethargy or loss of motor milestones in the young child. There may also be rapid progression and admission criteria to the ICU include respiratory failure, bulbar palsy, severe autonomic disturbance, or rapidly progressive weakness. Sensory loss is usually minimal and transient. Pain in the back and legs, possibly neurogenic in origin, is common and may be the presenting feature.[57] This pain may be severe and is often difficult to control. Papilloedema and encephalopathy occasionally occur.[58] The complications of deep-venous thrombosis and thromboembolism are not common problems in young children but may occur in adolescents.

INVESTIGATIONS

A lumbar puncture (LP) should be done ideally before treatment with intravenous immunoglobulin (IVIG) is commenced. CSF typically shows a WCC $<10\times10^6$, while CSF protein is usually raised but may be normal during the first week of illness. Nerve conduction studies may be normal if performed early. Neurophysiological criteria have been used to classify GBS subtypes according to either demyelinating or axonal neuropathies and whether or not both sensory and motor nerves are involved.[59] Anti-ganglioside antibodies are raised in some but not all patients.[60]

If there is uncertainty about the clinical diagnosis then brain and spinal cord imaging, as well as screening for infection, should be considered. Contrast-enhanced spinal MRI demonstrates contrast enhancement of spinal nerve roots and the cauda equina in most patients with GBS.[61,62]

MANAGEMENT

Adequate respiratory care is the basis of minimising morbidity and mortality in GBS. Up to one-third of patients require ventilatory support and, ideally, mechanical ventilation should be undertaken electively. Early indications are increased work of breathing, fatigue, poor cough, and progressive bulbar palsy. Hypercarbia is a late sign and should be avoided. In children who are old enough to cooperate, forced vital capacity (FVC) should be monitored during the progressive phase of the illness. Mechanical ventilation should be considered if FVC falls below 15–20 mL/kg. Careful frequent clinical assessment is necessary. Once

mechanically ventilated, many patients require some degree of hyperventilation to prevent ‘air hunger’. Although nasotracheal intubation is satisfactory initially, a tracheostomy should be performed if recovery is delayed. This will improve comfort and allow speech via the ventilator generating an air leak around the tracheostomy tube. Successful weaning is unlikely unless vital capacity exceeds 12 mL/kg and maximum negative inspiratory force is at least 20 cm H_2O (2 kPa).

Autonomic dysfunction is an important cause of morbidity and mortality in children with GBS. Airway manipulation or induction of anaesthesia, particularly in the presence of hypoxia, may provoke serious cardiac arrhythmias. Fluctuating blood pressure, urinary retention and gut dysfunction also occur.

Plasma exchange (PE) and intravenous immunoglobulin (IVIG) are effective therapies. The indications for either are rapid progression, respiratory insufficiency or weakness to the point of being unable to walk unassisted. The strongest evidence for these therapies is from adult trials.[63–65] Large trials adequately powered to separately test the efficacy of PE and IVIG in children have not been performed; however, a number of small retrospective studies have described local experiences with these immune therapies in children with mixed results.[66–70] As IVIG has significant potential technical advantages over PE, IVIG is generally the first-line therapy in children. Indications for IVIG are based on the degree of functional impairment and time from onset of symptoms. The indications are not influenced by the clinical or neurophysiological subtype or the results of antibody screening. There is no evidence to support sequential treatment using both PE and IVIG.[71,72]

Pain is a common feature of GBS and may have a neuropathic basis. Paracetamol, non-steroidal anti-inflammatory drugs are useful, while drugs to treat neuropathic pain including gabapentin, carbamazepine and amitriptyline may also be beneficial.

The problems of long-term ventilation in a conscious patient compounded by emotional immaturity, speech failure, fear of procedures and family disruption make the management of a child with GBS and their family particularly challenging. A sensitive team approach is essential.

PROGNOSIS

The prognosis in acute GBS may be better for children than for adults. Full recovery is likely if the time from maximal deficit to onset of recovery is less than 18 days. Complete recovery, despite a longer plateau phase, has been reported, however.[73] Good recovery can occur in patients who have required ventilation and the need for ventilation may not be a poor prognostic factor in children.[66] Those presenting with a subacute course are at risk of relapse and permanent motor deficits.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is defined as an episode of inflammatory central nervous system demyelination with polyfocal neurological deficits accompanied by encephalopathy (behavioural change or altered consciousness). Clinical features include encephalopathy, which is required to make the diagnosis, ataxia, hemiparesis, seizures, upper airway respiratory obstruction and polyfocal neurological deficits.[74] The encephalopathy varies in severity from subtle signs of irritability and headache to life-threatening coma and decerebrate rigidity. Severe cases frequently require support with a period of mechanical ventilation.[75]

ADEM is often preceded by a viral infection or vaccination. The most common agents responsible for the prodromal phase include Epstein–Barr virus, cytomegalovirus, herpes simplex virus, and *Mycoplasma*; however, in the majority of cases a specific agent cannot be identified. The condition is thought to result from an autoimmune process with formation of antibodies against myelin.

INVESTIGATION

Lumbar puncture should be performed to exclude infectious encephalomyelitis. There may be a modest elevation of the CSF white cell and red cell count. CSF oligoclonal bands and raised CSF immunoglobulin levels occur more commonly in multiple sclerosis than in ADEM.[74] MRI with T2 and FLAIR show bilateral asymmetrical hyperintense demyelinating lesions. The lesions predominantly involve the white matter at the grey–white matter junction; however, the grey matter may also be involved. The size of lesions varies from punctate to large tumefactive (puffy/swollen) mass-like lesions.[76] Some patients with ADEM have normal MRI findings on initial presentation but develop features typical of ADEM if the study is repeated several weeks later. In some patients the MRI changes first appear at a time when clinical improvement is occurring.

MANAGEMENT

Although there are no randomised therapeutic trials in ADEM, high-dose corticosteroids are considered the treatment of choice. Intravenously methylprednisolone 20–30 mg/kg/day (maximum 1 g/day) for 3–5 days followed by oral prednisolone tapered over 2–3 weeks often results in rapid clinical improvement. Other treatment options include intravenous immunoglobulin (2 g/kg intravenously for 2–3 days) and plasmapheresis.[74]

OUTCOME

Most children with ADEM recover completely although a small percentage of children have significant

neurological and neuropsychological sequelae. Rarely ADEM is fatal. Approximately 20% of children initially diagnosed with ADEM experience a recurrence of neurological symptoms and subsequently receive the diagnosis of multiple sclerosis.[77]

METABOLIC ENCEPHALOPATHY

Approximately 0.1% of babies have an inborn error of metabolism. Acute encephalopathy is one of the many ways neurometabolic diseases present in childhood.[78,79] In general, acute presentations occur in the neonatal period and early infancy. Symptoms are often vague and include lethargy, poor feeding and vomiting. Older infants and children more commonly present with a chronic encephalopathy, with features that may include seizures, long-tract signs, visual impairment and loss of milestones.

APPROACH TO DIAGNOSIS

A careful history and examination may elicit clues to a possible metabolic problem. Family history and history of drug exposure are extremely important. Valproate, in particular, has been associated with liver dysfunction and encephalopathy. The following readily available investigations are useful to allow a broad categorisation and direct further detailed investigations: blood gas analysis, blood sugar, serum ammonia, serum lactate, plasma amino acids, urine metabolic screen, and urine ketones. While lactic acidosis and hypoglycaemia can occur in a number of disease states including sepsis, persisting abnormalities require further investigation. Lactic acidosis can be further assessed with measurement of lactate/pyruvate ratio. Figure 109.1 provides an algorithm proposed by Ellaway and colleagues to direct the investigation of metabolic disease presenting in the newborn period based on the metabolic abnormalities detected from baseline investigations.[80] This is best done in collaboration with a metabolic disease specialist or a clinical biochemist.

MANAGEMENT

Initial management includes elimination of toxic metabolites and administration of calories to switch

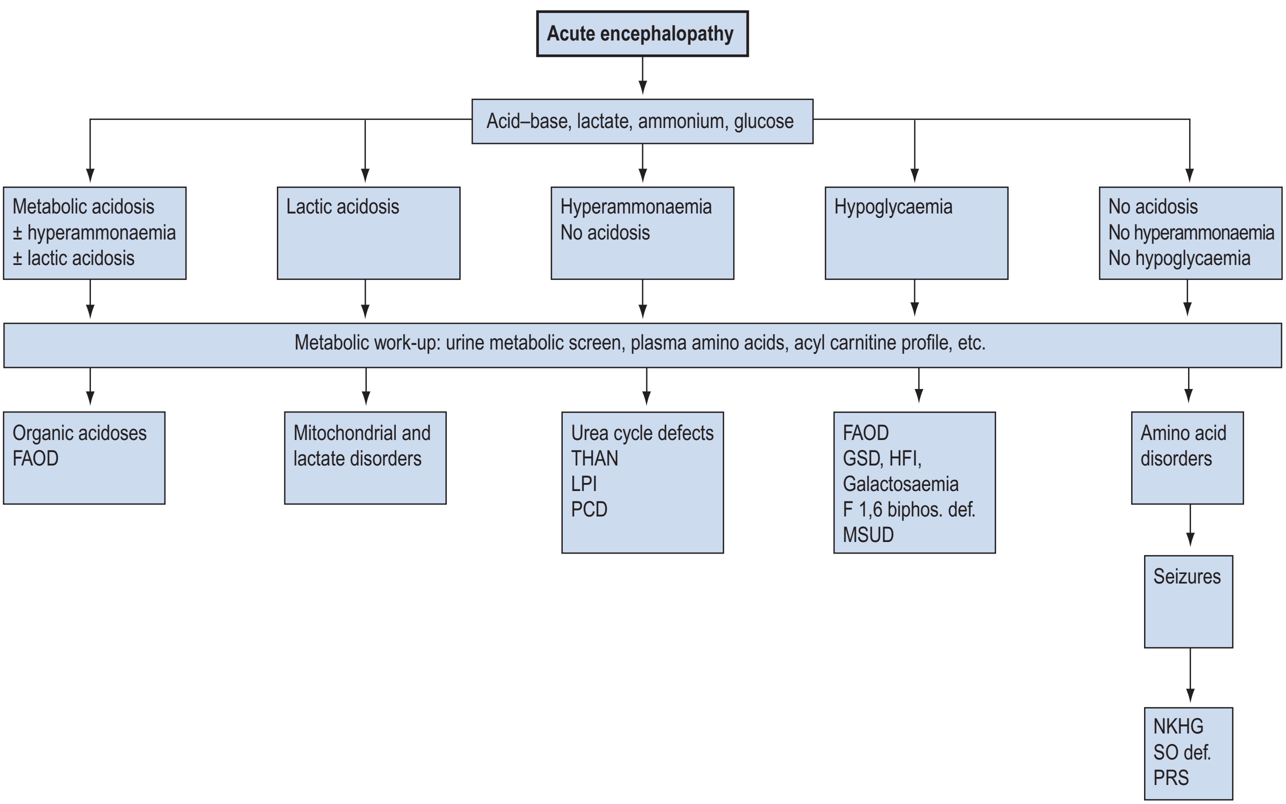

Figure 109.1 Flow diagram to guide investigation of inborn errors of metabolism presenting in the newborn period. FAOD=fatty acid oxidation disorder; F1,6 biphos. def., =fructose 1,6 biphosphatase deficiency; GSD=glycogen storage disorder; HFI=hereditary fructose intolerance; LPI=lysinuric protein intolerance; MSUD=maple syrup urine disease; NKHG=non-ketotic hyperglycinaemia; PCD=pyruvate carboxylase deficiency; PRS=pyridoxine-responsive seizures; SO def.=sulphite oxidase deficiency; THAN=transient hyperammonaemia of the newborn.

off catabolism. Metabolic derangements such as acidosis and hypoglycaemia should be corrected. The role of ICP monitoring for acute intracranial hypertension is controversial; however, patients with suspected raised ICP and unconscious patients should receive standard modalities of support including intubation and mechanical ventilation. Hyperammonaemia should be managed by stopping enteral feeds to limit protein intake. Agents such as arginine and sodium benzoate can be administered to increase ammonia metabolism. Providing calories intravenously in the form of glucose and fat limits the extent of catabolism and thereby helps to curtail the metabolic crisis. Dialysis is used to control severe hyperammonaemia and acidosis. Continuous venovenous haemodiafiltration is more effective than peritoneal dialysis.[81]

SPINAL INJURY

INCIDENCE

Paediatric spinal trauma is relatively rare, comprising <5% of all spinal injuries. Approximately 5% of children with severe head trauma will have a cervical spine injury. However, a high proportion of children who die following motor vehicle trauma, particularly those who suffer immediate cardiorespiratory arrest, or who die before arrival at hospital, have disruption of the spinal cord above C3, particularly at the cervico-medullary junction.[82,83]

AETIOLOGY

The most common causes of paediatric spinal trauma are motor vehicle crashes, as either a pedestrian or passenger, falls and diving injuries. Sports-related injuries are uncommon.

PATHOPHYSIOLOGY

The patterns of spinal injury in children differ from those seen in adults in many ways. Spinal cord injury without radiographic abnormality (SCIWORA) occurs almost exclusively in children (20–60% of spinal cord injuries). It is associated with a high incidence of complete neurological deficit. Spinal injury in the first decade of life occurs most commonly in the first two cervical segments, with atlanto-axial rotatory subluxation, bony or ligamentous injuries, or SCIWORA and severe cord injury. Although not as common as upper cervical injuries, lower cervical injuries (below C4) do occur in young children,[84] while injury may occur at more than one level. Atlanto-axial rotatory subluxation is rarely associated with neurological deficit while ligamentous injury is more likely to be associated with permanent neurological deficit than high cervical fractures.[85] As the bony spine matures, the pattern of injury becomes more adult-like, with lower cervical and thoracic injuries seen in the second decade.[86,87]

CLINICAL FEATURES

The immediate effects of spinal cord damage are similar at any age. Frequently an associated head injury can render clinical assessment extremely difficult; confirmation of cord injury is sometimes delayed. Clues to the diagnosis in the unconscious patient include:

- flaccidity, immobility and areflexia below the level of the lesion
- hypoventilation with paradoxical chest movement; this occurs in the absence of airway obstruction where the intercostal muscles are paralysed and the phrenic nerves are intact
- apnoea with rhythmic flaring of the alae nasi (Duncan's sign), seen when the lesion is above C3
- hypotension with inappropriate bradycardia and cutaneous vasodilatation below the level of injury, due to absent spinal sympathetic outflow
- priapism, which occurs frequently.

There may be visible or palpable evidence of trauma to the spine and surrounding soft tissues, including retropharyngeal or retrolaryngeal haematomas. Spinal shock is common with temporary complete loss of function. As this resolves after 3–5 days, reflexes progressively return, usually starting with bulbocavernosus and anal reflexes. Incomplete lesions, including the Brown–Sequard cord hemisection, and anterior and central cord syndromes may become apparent at this stage.

INVESTIGATIONS

Resuscitation, including emergency intubation, should not be delayed to perform X-rays. However, the entire spinal column should be X-rayed subsequently, to demonstrate the presence of subluxation, fractures, or dislocations. MRI is useful both in the acute setting and in assessment at later stages and is now accepted as the standard for identifying haemorrhage, contusion or compression of the cord. CT produces better definition of bony injuries, and may also show cord involvement by haematomas, bone fragments and foreign bodies. SCIWORA was defined in an era before MRI was routinely available. In the majority of children with SCIWORA, MRI will also be normal; however, if intramedullary lesions are demonstrated with MRI, permanent neurological deficits are more likely.[88,89] Somatosensory evoked potentials may be useful to evaluate the integrity of the spinal cord, particularly in the comatose patient.

MANAGEMENT

Achieving control of airway, ventilation and circulation is always of first priority. If tracheal intubation is indicated, and if stability of the neck is unknown, skilled assistance is necessary to immobilise the head and neck

and prevent flexion or extension. Because of the sympathectomised state in high cord injuries, a relatively low blood pressure can be expected even after hypovolaemia is corrected. Significant hypotension becomes more likely the higher the lesion and the younger the patient. Haemodynamic support with a vasoconstrictor such as norepinephrine (noradrenaline) is useful if hypotension is problematic following restoration of intravascular volume. As up to 20% of patients will have multiple trauma, many will require major surgical procedures, during which the spinal cord must remain protected. If muscle relaxants are required 2–3 days following the injury, suxamethonium is contraindicated owing to the risk of fatal hyperkalaemia.

The use of steroids is controversial and there are no studies specific to children. Two randomised controlled trials in adults demonstrated that high-dose methylprednisolone administered soon after injury improved outcome.[90–91] These studies have significant limitations and the results have not been universally accepted.[92–94]

As with brain injuries, preventing secondary injury is vital. Adequate perfusion of the cord should be ensured, as autoregulation of blood flow is lost after trauma. Immobilisation can be maintained by skull tongs with axial traction or external bracing. Operative intervention is controversial with little evidence of neurological improvement from decompressive surgery. Laminectomy and decompression in children with complete cord injuries carry significant mortality.

The incidence of venous thromboembolism after spinal injury in adolescents approaches that in adults and therefore patients in this age group should receive standard prophylaxis. Venous thromboembolism is rare in prepubertal children (approximately 1%), and the risk–benefit ratio of routine prophylaxis in this age group is unknown.[95] There should be early consultation with a specialised spinal injuries unit. Optimal rehabilitation requires a team of orthopaedic and neurosurgeons, rehabilitation specialists, nurses, physiotherapists, occupational therapists, psychiatrists, social workers and schoolteachers.

PROGNOSIS

The prognosis of all spinal injuries in children may be better than in adults. In one series of 113 children with spinal column injuries, 55 (48%) had no neurological deficit, 38 (34%) had an incomplete deficit, and of these 23 (20%) made a complete recovery and 11 (10%) improved. The remaining 20 (18%) children had a complete cord injury and, of these, 4 improved and 3 died.[82] In a smaller series 44% had neurological deficits, SCIWORA was seen in 21% and 11% of injuries were immediate, complete and permanent. Of the 18 children with SCIWORA, 4 had a permanent, complete deficit.[85]

Paediatric trauma

Kevin McCaffery

In developed countries, trauma continues to be the leading cause of death in children over 1 year of age.[1] When the additional vast burden of morbidity is added, it is clear that this spectrum of pathologies deserve urgent, ongoing and proactive attention.

Paediatric trauma is *complex* – an easily overlooked concept, particularly for those who mostly care for traumatised adults, yet this understanding is crucial to the provision of an effective paediatric trauma service.

This chapter is written principally from the viewpoint of the intensive care specialist faced with a seriously injured child. As intensive care involvement frequently begins with a request to assist with pre-hospital care or retrieval, key management priorities for this phase are included in the wider intensive care discussion.

OPPORTUNITIES FOR INTERVENTION

Death following trauma has long been considered to have a trimodal distribution (immediate, early <4 hours, and delayed). Later publications challenge this pattern of distribution, though the concept remains philosophically useful. Pre-hospital health care practitioners focus on the pre-hospital phase of trauma management, whereas hospital-based acute practitioners are more cognisant of the immediate and intermediate phases of trauma care. Taking a bigger picture, however, it is clear that there are a number of definable phases in the journey of a severely traumatised patient requiring different types of intervention (**Fig. 110.1**). A mature 'trauma system' or 'trauma team' would be expected to be cognisant of and active in all phases of trauma management from injury to outcome.

Trauma

This phase is commonly unexpected and sudden, with little opportunity to mitigate harm. All useful interventions here are derived from those emplaced during the pre-trauma phase. The most important interventions in the management of trauma are those that prevent injury occurring in the first place.

Pre-trauma

In a number of areas, legislation and public safety campaigns have led to decreased morbidity and mortality. Notable successes lie in the areas of motor vehicle legislation (seatbelt laws, drink–driving legislation, speed restriction and vehicle design), bicycle legislation (cycle helmets and education), water safety (pool fencing, water safety and swimming lessons) and burn reduction (smoke detectors, limitation of hot water temperature).

By any measure, politicians and legislators rank amongst the most effective members of the expanded 'trauma team,' though it should be noted that they can be susceptible to influence by pressure groups, as exemplified by the turbulent (and ongoing) evolution of swimming-pool fencing regulations in Australia.[2]

Pre-hospital care

Two models for pre-hospital care predominate in the Western world.[3] In the United States, the prevailing concept is that of 'scoop and run' by paramedical staff to designated 'trauma centres'. The principal driver of this process was the decreased battlefield mortality seen between World War II (4.5%) and the Vietnam War (1.9%). A number of innovations contributed to this decrease, but increasing rapidity of casualty evacuation to well-equipped surgical hospitals was a key feature.

Conversely, the model adopted by several European and Scandinavian countries involves use of paramedic-crewed ambulances supported by a well-developed network of physician-manned ambulances, essentially mobile intensive care units.

No robust data currently exist to demonstrate the superiority of one system over the other, for it is likely that differences in such variables as geography and distance, prevalence of penetrating versus blunt trauma and cost and resource implications will favour different models in different areas.

Furthermore, in comparison with adults, seriously traumatised children are more likely to require secondary transfer to a paediatric trauma centre after initial stabilisation is undertaken, owing to concentration of paediatric expertise in a smaller number of centres.

THE DEVELOPMENT OF 'TRAUMA TEAMS, CENTRES AND SERVICES'

The concept of multidisciplinary teams and institutions with specific interest and expertise in trauma

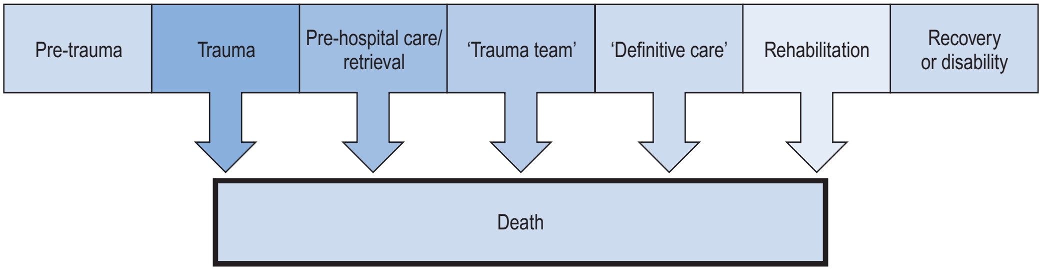

Figure 110.1 Phases of severe paediatric trauma.

management began to develop in the 1950s and 1960s. Currently, most developed countries have accreditation processes for trauma services and designate different centres by 'level' based on their capabilities.

In addition to doctors and nurses from acute specialties such as the emergency department, surgical subspecialties, anaesthesiology and critical care, the wider multidisciplinary team frequently includes trauma coordinators, research staff and rehabilitation specialists such as physiotherapists, psychologists and social workers. Similarly, the remit of trauma teams, centres and services has expanded beyond simple care of the traumatised patient, and now includes data collection and analysis, development of injury-prevention strategies and coordination of regional trauma services.

There is growing evidence that development of trauma teams, centres and services improves outcomes for injured adults[4] and children.[5] Opinion is more divided on whether or not outcomes for seriously traumatised children are improved when managed in designated paediatric trauma centres compared with adult trauma centres, however.[6,7]

SPECIFIC PAEDIATRIC TRAUMA PRESENTATIONS

Differing mechanisms of injury may be associated with specific patterns of injury in both children and adults, though anatomical and physiological differences between age groups will alter the pattern seen. Children requiring intensive care admission will have serious injury to one or more of the following.

TRAUMATIC BRAIN INJURY

Brain injury, resulting either directly from trauma or indirectly from hypoxic–ischaemic insult, accounts for the majority of deaths and long-term severe morbidity in paediatric trauma. Once the insult has occurred, management is entirely focused on prevention of secondary insults and further damage. Conventionally this involves control of intracranial hypertension, defence of cerebral perfusion pressure (CPP) and minimisation of injurious factors such as seizures, hypo- or hyperglycaemia and fever. An overview of this topic is provided below, but those wishing a comprehensive review of the current evidence base behind current management of paediatric traumatic brain injury (TBI) are directed to guideline documents published by the Brain Trauma Foundation.[8]

PAEDIATRIC TBI: ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

Adult brain volume is reached around 6 years of age, whereas skull growth continues until around 16 years of age. Children thus have less room for brain swelling within the rigid skull. This is compounded by differences between children and adults in adaptive mechanisms to defend against raised intracranial pressure, including smaller relative cerebrospinal fluid volumes, higher intracellular concentrations of sodium and impaired ability of neurons to extrude sodium. In addition to the propensity of smaller children to raised intracranial pressure (ICP), cerebral perfusion pressure may be further compromised by the similarities in autoregulation of cerebral blood flow between small and larger children, affording smaller patients less safety margin.[9]

NEUROLOGICAL ASSESSMENT AND MONITORING OF CHILDREN

Priorities of the assessment process are as follows:

- to benchmark neurological function over time
- to identify lesions and problems requiring treatment
- to identify prognostic markers.

Neurological assessment in childhood presents challenges in compliance with examination. An appreciation of child development and the use of age-appropriate tools (such as a modified Glasgow Coma Score) greatly facilitate this assessment. Assessment is best done as a process involving frequent clinical assessments over time, supplemented where indicated by targeted investigations such as computed tomography (CT) or magnetic resonance imaging (MRI).

Invasive monitoring of intracranial pressure and arterial blood pressure allows identification of deleterious intracranial pressure and permits calculation of cerebral perfusion pressure.

Intracranial pressure monitoring should be zero calibrated at the tragus of the ear with the patient inclined 30°. The target ICP threshold requiring management has not been defined in paediatrics, but current

evidence would support an upper value of 20 mmHg (2.66 kPa). Lower values of 15–20 mmHg (2–2.66 kPa) may be more appropriate for small infants.

Cerebral perfusion pressure is defined as *mean arterial pressure (MAP) – mean intracranial pressure*. Mean arterial pressure should be zero calibrated at the level of the right atrium with the patient inclined 30°. It should be noted that the difference in zero level between ICP and MAP will not give a true CPP as stated and that the error will increase with increasing patient length. It does, however, allow for standardisation of measurement within routine clinical practice. Target CPP thresholds requiring management have not been defined in paediatrics, but current evidence would support a CPP target of between 40 and 50 mmHg (5.32 and 6.65 kPa).

MANAGEMENT PRIORITIES IN THE CHILD WITH HEAD INJURY

Management of paediatric neurotrauma is entirely focused on minimising secondary injury to neurons. Principles include the following:

Management of intracranial pressure

This involves manipulation of intracranial contents as described in the Monroe–Kellie hypothesis. Thus, the intracranial volume lying within the incompressible skull is composed of brain tissue, blood and cerebrospinal fluid (CSF), and any increase in the volume of one of the components must be compensated for by a reduction in volume of the others. Interventions manipulate the following volumes as follows:

- **Blood compartment:** decreasing intracranial blood volume may be tackled in three ways:
  - *Extravasated blood:* significant collections require surgical evacuation.
  - *Venous compartment:* venous drainage may be optimised by avoidance of venous obstruction (spinal collar, internal jugular lines, excessive PEEP) and patient positioning (30° head up, head midline). One small paediatric study demonstrated that increased head-up bed angle decreased ICP but not CPP.[10] Judicious sedation and muscle relaxation decrease the incidence of coughing, shivering and asynchrony with mechanical ventilation.
  - *Arterial compartment:* manipulation of this compartment requires brain tissue with preserved autoregulation to P_{CO_2}, pH, viscosity and metabolic demand. Thus, mild hyperventilation will vasoconstrict these areas, thereby decreasing the volume of the arterial bed. Prolonged or extreme hypocarbia should be avoided due to the potential for ischaemia, particularly to vulnerable penumbral areas of injured brain. Hypercarbia must also be avoided as it will increase ICP. Volume-controlled ventilation may permit more stable blood gases.

  Osmotic agents such as 3% (hypertonic) saline or mannitol exert a rheological effect by dehydrating red blood cells. The resultant decrease in blood viscosity permits a degree of cerebral vasoconstriction while still meeting metabolic demands. Use of hypertonic saline in preference to mannitol appears better supported in the literature to date.

  Decreasing neuronal metabolic demand can lower ICP. Seizures should be controlled and hyperthermia avoided. Second-tier therapies such as barbiturates and therapeutic hypothermia (32–33°C) have been demonstrated to decrease refractory raised ICP. However, both have potential serious side-effects and limited evidence to support routine use. Recent RCTs of therapeutic hypothermia versus normothermia in children have failed to demonstrate differences in functional outcome, and either no difference in mortality[11] or a trend towards increased morbidity and mortality in the cooled group.[12] A further study – Cool Kids – was stopped early on grounds of futility and has yet to publish its results.
- **CSF volume:** external ventricular drainage of the lateral ventricles allows decrease in CSF volumes in addition to ICP monitoring. This may not be practical if the ventricles have already been effaced, however.
- **Brain volume:** osmotherapy with hypertonic saline or mannitol may decrease intracranial volume by dehydrating neurons in areas with an intact blood–brain barrier.

A fourth mechanism for decreasing intracranial pressure is to undertake a decompressive craniectomy. Although recent randomised controlled trial data in adults demonstrated decreased ICPs in patients receiving this intervention, the operated group also experienced worse outcomes.[13] In paediatrics, although a number of small studies have demonstrated the utility of decompressive craniectomy in reducing raised ICP, evidence of effect on outcomes is lacking.[4,14]

Centres with limited experience in managing paediatric neurotrauma may benefit from structured guidelines, an example of which is the Scottish Intercollegiate Guideline Network (SIGN) guideline 110: Early management of patients with a head injury.[15]

A number of prognostic markers in head injury have been identified. These include the Glasgow Coma Scale, Injury Severity Score and initial hypotension.[16] Of note, the motor score component of the Glasgow Coma Scale may be as predictive as using the entire score.[17]

THORACIC TRAUMA

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The immature rib cage is largely cartilage, and ossifies through childhood. Compliant ribs allow transmission of greater impact energy to underlying viscera,

allowing severe contusion without necessarily fracturing. Furthermore, the compliant infant chest and relatively transverse ribs impair tolerance of upper airway obstruction.

Increased basal metabolic rate and reduced functional residual capacity result in a more rapid onset of hypoxaemia in younger children, and this may be compounded in infancy by physiologically low haemoglobin.

ASSESSMENT AND MANAGEMENT OF THORACIC TRAUMA

Immediate assessment of a child with thoracic trauma is focused on identifying life-threatening injuries, which include:

- large airway disruption
- tension pneumothorax
- open pneumothorax
- massive haemothorax
- flail segment
- cardiac tamponade.

Management is guided by the specific findings from the primary survey, but severe thoracic trauma is likely to require intubation and ventilation, with pleural or pericardial drainage as indicated. Rare but severe injuries that may be difficult to detect during resuscitation and therefore require a high index of suspicion would include major vascular injuries, thoracic spinal injuries and traumatic diaphragmatic hernia.

A chest X-ray is a component of routine trauma assessment and may be supplemented as indicated by ultrasound assessment and computed tomography. Angiography of the great vessels may be undertaken formally or as part of the CT scan. Serial arterial gases guide requirements for ventilatory support.

ABDOMINAL TRAUMA

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The orientation of the compliant ribs in small children affords less protection to the disproportionately large liver and spleen when compared with older children or adults, while the shallow pelvis leaves the bladder at similar risk.

Small children are difficult to examine. They are also prone to aerophagia with distension of the stomach increasing emesis risk, and in some cases leading to diaphragmatic splinting.

Paediatric abdominal trauma is largely blunt in nature, and solid organ injury occurs far more commonly than hollow visceral injury. Certain mechanisms of injury should lead to the suspicion of characteristic injuries. These include handlebar into epigastrium associated with pancreatic or duodenal injury, lap-belt injuries in motor vehicle accidents leading to small bowel rupture, diaphragmatic injury or Chance fracture (flexion) of the lumbar spine. Given the difficulties in diagnosis, a high index of suspicion for abdominal injuries in trauma in children is essential.

When suspicion of abdominal injury exists, repeated clinical examination over time is supplemented by plain abdominal X-rays, ultrasonography, or CT scanning as indicated. In haemodynamically stable blunt paediatric trauma, focused abdominal sonography for trauma (FAST) currently lacks the sensitivity and positive predictive power for use as a definitive screening tool.[18] CT scanning of the abdomen is considered the 'gold standard'.

In most paediatric trauma involving the abdomen, management is expectant. Laparotomy is generally reserved for the following situations:

- penetrating injury
- hollow viscus perforation (bladder rupture/pneumoperitoneum)
- haemodynamic instability despite adequate fluid resuscitation (≥40 mL/kg)
- peritonism (later sign)
- diaphragmatic rupture.

Even high grades of splenic or hepatic laceration may be managed conservatively, provided assessment is frequent and the patient is managed in a facility with the ability to intervene surgically at short notice.

SPINAL INJURY

Spinal injury in children is rare, often difficult to diagnose and potentially devastating if missed. Challenges include the anatomical and physiological differences between adults and children, which change the types of injury commonly seen, and make radiological interpretation difficult and clinical examination challenging. Furthermore, as spinal injuries are rare, the benefits of managing injured children in a paediatric facility must be balanced against the expertise available in adult spinal injury centres.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

Differences in the immature spine and the proportionally more massive head change patterns of paediatric injury compared with adults. High lesions from the occipitoaxial junction to C3 are more common than the more typical C4–C5 lesions seen in older patients. In addition, the elasticity of paediatric ligaments may lead to the phenomenon of spinal cord injury without radiological abnormality (SCIWORA), present in 17–43% of paediatric cord injuries.[19, 20]

Mechanisms of injury change at different stages of development, with increasing incidence of sports injuries in older children.[19]

Pre-verbal children present challenges in assessment and even older children may regress and become

uncompliant with clinical examination. Additionally, progressive ossification of the spine during childhood renders radiological interpretation problematic.

Spinal cord injury in children, particularly when very young, leads to an increased incidence of scoliosis, tracheostomy (due to the increased incidence of high lesions) and progressive pulmonary insufficiency.

ASSESSMENT AND MANAGEMENT

The possibility of spinal cord injury should be considered in all significant trauma, and particularly following motor vehicle accidents, rapid deceleration injuries or in the presence of multisystem trauma, head injuries, other injuries above the clavicle or abnormal neurological signs.

The first priority is spinal immobilisation, which should occur in the pre-hospital phase.

Clinical assessment is supplemented by plain radiography in the initial assessment. In severely traumatised patients, early neck clearance by clinical examination is not possible, and even plain radiography in three views – which has 94% sensitivity – may fail to detect SCIWORA. Computerised tomography and magnetic resonance imaging contribute additional information, but still will not detect all lesions even when motor signs are present.[21]

Spinal precautions must be maintained until either the neck is deemed to be uninjured or stable on clinical and radiological grounds, or until fixation has occurred.

Use of steroids or hypothermia in paediatric spinal injury is not supported by evidence at this time and is not regarded as mainstream therapy.

Early feeding, gastric protection with proton pump inhibitors, bowel care, care of skin and pressure points and prevention of contractures are important interventions if not precluded by other injuries. Similarly, early access to rehabilitation services may improve functional outcomes.

BURNS

Burns are a common cause of accidental death in childhood.[22] Younger children predominantly suffers scalds, whereas older children are more likely to present with flame burns. Burns are often included within the extended scope of trauma as many mechanisms leading to burns are also associated with traumatic injury (motor vehicle accidents, explosions, etc.). Additionally, when confronted by the prospect of burning, patients will frequently risk or incur traumatic injuries during attempted escape.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The increased surface area/weight ratio of children compared with adults leads to a number of problems. Fluid loss from the burn may rapidly lead to dehydration, and any surface cooling undertaken increases the risk of iatrogenic hypothermia. Furthermore, alteration in body proportions from birth to adulthood mandates the use of specific methods for estimating paediatric burn surface area such as the modified Lund and Browder chart. Estimated burn surface area may be made using the area of the child's palm with outstretched fingers. Each such area corresponds to 1% of body surface area (areas of erythema should *not* be included in estimation of burn surface area).

Mechanisms of injury and patterns of burn are different to adults. Small, curious children below the level of kitchen work-surfaces are commonly scalded on the face, head and upper body when pulling pans and kettles down, an injury exacerbated by a disproportionately large head. Similarly, severe hand injuries may follow attempts to grasp hot objects or, in older children, fireworks.

The small paediatric airway is particularly vulnerable to upper airway obstruction following smoke inhalation.

Finally, paediatric burn injury may result in profound and progressive disability. Thick burn scarring may distort normal somatic growth, and psychological scarring may severely compromise social development.

INITIAL MANAGEMENT

First aid for burns involves cooling for no longer than 20 minutes, using tepid (not cold) water. As burns and trauma frequently coexist, a trauma primary survey (**a**irway+cervical spine control, **b**reathing, **c**irculation, **d**isability) should be rapidly carried out. The findings of particular relevance are listed in **Box 110.1**.

Box 110.1 Primary survey findings in burns

Airway: Is there actual or impending airway compromise?
- History of burn in enclosed space
- Facial burns/swelling
- Stridor or respiratory distress
- Carbonaceous sputum

Breathing: Is there respiratory compromise?
- Respiratory distress
- Cyanosis
- Thoracic or upper abdominal burns
- Circumferential thoracic burns

Circulation: Is there evidence of hypotension or hypovolaemia?
- Calculate burn surface area, ascertain time of injury to facilitate fluid management
- Shock from associated injuries?

Disability (neurology): Is there impairment of conscious level?
- Carboxyhaemoglobin level?
- Other toxins from smoke, e.g. cyanide?
- Associated head injury?

Once cooled, burns should be covered with sterile, non-occlusive dressings. Creams or ointments should not be applied unless advised by the local burns surgeon. Adequate hydration is required to optimise perfusion of injured areas. Fluid regimens such as the Parkland, Brooke or Galveston formulae (or modifications thereof – see **Box 110.2**: modified Parkland formula) are routinely initiated.

Pain relief with opioids and consideration of need for escharotomy where burns are circumferential should occur early, and be repeated frequently as required.

DEFINITIVE CARE

Major burns are best managed by burns centres. Burned patients in the intensive care unit are commonly ventilated for inhalational injury or to facilitate pain management. These patients require meticulous attention to fluid and electrolyte balance, nutrition, analgesia and wound care. Frequent trips to the operating room for dressing changes, wound debridement or skin grafting are expected. Routine antibiotics are not indicated, but patients require close monitoring for signs of evolving sepsis. Wound swabs and debrided tissue for culture assist in surveillance for sepsis.

NON-ACCIDENTAL INJURY

A significant proportion of children presenting with trauma will have been injured deliberately or through neglect, often by a parent or care giver. Although confrontational, this is an important diagnosis to consider as it has profound implications for the future safety of both the affected child and the family at large. In many countries there is an obligation on health care practitioners to report concerns to child protective services.

Although presentations are highly variable and may be covert, there are a number of risk factors that may increase the likelihood of an injury being factitious, as follows.

INJURY CHARACTERISTICS

- Delayed presentation of injury
- Injury inconsistent with history provided
- Injury inconsistent with child's developmental stage
- Injury with suspicious pattern as follows:

Bruising

- Specific patterns, e.g. belt buckle, handprints, loop marks from flex
- Multiple bruises of differing ages

Fractures

- Fractures of different ages
- Specific patterns, e.g. spiral humeral fracture

Burns

- Specific patterns, e.g. immersion (glove/stocking/thighs, sometimes sparing buttocks and backs of knees), cigarette or cooker-top
- Burns of different ages

Others

- Retinal haemorrhages
- Bite marks
- Bleeding from, or trauma to, anus or genitalia.

In addition to features of the injury, there are numerous patient and social factors increasing the risk of factitious injury, which include amongst others:

- *patient factors:* young age, congenital anomalies, physical or intellectual disability, adoption, etc.
- *social factors:* young or single parents, unstable family situations, substance abuse and parents who were themselves abused. Environmental stresses include divorce or financial/legal/professional difficulties.

SUMMARY

Paediatric trauma differs in important respects from trauma in adults, and is associated with a vast burden of morbidity and mortality. The development of dedicated paediatric trauma teams or services appears to be associated with improved outcomes, and represents a powerful mechanism for developing and disseminating regionally appropriate protocols, undertaking research and engaging legislators.

Box 110.2 Modified Parkland formula

Patients require resuscitation fluids + maintenance fluids.

Resuscitation fluids: 3–4 mL Hartmann's solution × weight (kg) × %total body surface area burned.

Half of this volume is given in the first 8 hours from time of injury, with the remainder given over the subsequent 16 hours.

Maintenance fluids (commonly Hartmann's + 5% dextrose): 100 mL/kg/day for the first 10 kg, 50 mL/kg/day for the next 10 kg then 20 mL/kg/day for every kg thereafter.

- Formula is used in burns exceeding 15% total body surface area.
- Fluid boluses given during resuscitation may be subtracted *unless* pre-existing dehydration or associated injuries exist.
- Aim is for *adequate* urine output: 1–2 mL/kg/h < 30 kg; 0.5–1 mL/kg/h > 30 kg

Withholding and withdrawing life-sustaining medical treatment in children

James Tibballs

Withholding and withdrawing life-sustaining medical treatment is common in hospitals, particularly in intensive care units. Usually, decisions regarding limitation of therapy are based on ethical considerations and derived by discussion and mutual agreement between parents and clinicians. However, disputes sometimes arise. When such disputes are settled in court, the judgements constitute common law.

All common law cases have been decided in the child's 'best interests', which is a nebulous term. Although each case has its own circumstances, a composite view reveals three legal and hence ethical criteria for 'best interests'. These are based on the present and future '*quality of life*', '*futility*' of present treatment and a comparison of '*burdens versus benefits*' of present and future treatment and its discontinuance. These principles may facilitate difficult decisions. This chapter considers the principles in such legal cases, which serve as the ethical basis for withholding and withdrawing life-sustaining medical treatment.

BACKGROUND LEGALITIES

Although no legislation exists, judgements in common-law cases on withholding or withdrawing life-sustaining treatment establish the legal basis for limitation of medical treatment. Common-law cases often involve disputes between parents and doctors.

Palliative care cannot lawfully be withheld or withdrawn. Such care includes provision of reasonable medical procedures for relief of pain, suffering and discomfort, and the reasonable provision of food and water. However, artificial provision of food and water such as by nasogastric tube, gastrostomy or intravenous administration is medical, not palliative, care and may be legally withdrawn.

Withholding and withdrawing of life-sustaining medical treatment occurs in paediatric institutions, particularly in intensive care units.[1–7] When the parents and doctors agree to withhold or withdraw treatment, their decisions are usually made on ethical grounds. However, disagreements between parents and hospital staff, and indeed between hospital staff, sometimes arise because of differences in ethical opinions. This is not surprising since one's ethical position is derived from diverse social, cultural, religious, moral and familial influences.

The common ethical and legal mantra for withholding and withdrawing treatment is the so-called 'best interests' of the child. This term, somewhat nebulous, is enshrined in, but not clarified by, section 68F of the Family Law Act 1975 (Cth), in which courts are directed to determine a child's 'best interests'.

Although the 'best interests' considered by courts in each case are specific to the circumstances of the child, when all cases are considered together three recognisable circumstances permit lawful withholding or withdrawing treatment. Several 'withholding' cases have come before Australian courts but, as only one case of withdrawing treatment from children (Baby D) has been considered, it is necessary therefore to consider a few cases from other jurisdictions with similar systems of law.

Other legal requirements in this setting are presumed. These include:

- sanctity of life
- withholding and withdrawing of life-sustaining treatment are omissions not acts
- withholding and withdrawing treatment are legally equivalent
- any deliberate attempt to shorten life or cause death is a criminal act
- euthanasia either active or passive is unlawful
- competent persons, who may include teenagers, have the right of self-determination
- parents, as legal guardians, make decisions on behalf of their child, but they cannot demand a particular treatment, nor demand that a particular treatment be withdrawn or withheld, nor withhold consent for treatment if not in the child's 'best interests'
- a doctor cannot be ordered to provide treatment not in the child's 'best interests'
- sedation or analgesia may be administered with the purpose of relieving pain, suffering and distress, but which may also unintentionally shorten life
- death following lawful withholding or withdrawal of treatment is due to the underlying disease
- parents and doctors may together decide to withhold or withdraw treatment in a child's 'best interests', but neither should do so alone.

Although ethical standards and clinical guidelines are not legally enforceable, adherence to these may be

scrutinised by courts in the context of meeting an appropriate standard of care according to the codes of practice of professional bodies or in relation to established medical practice.[8] It is obvious that ethical and legal principles are interdependent. It would be difficult, but not impossible, to imagine that legal judgements would be not be ethical and vice versa. Each espouses almost identical positions. Nevertheless, an occasional judgement may astound physicians, as for example the case of In the matter of baby K,[9] in which a judge ruled that mechanical ventilation could not be discontinued for an anencephalic infant.

QUALITY OF LIFE

That the future quality of life could be considered a factor in a decision to withhold or treatment was foreshadowed in Australia by the Victorian case of Baby M. Although the concept had already been accepted in Britain, it had been originally rejected in the Australian case of Re F; F v F.

RE F; F v F

This case,[10] concerning an infant with spina bifida, was brought hurriedly before the court in a father's affidavit, which (disputed by the mother) claimed that his infant was being denied sustenance and sedated for the apparent purpose of permitting or causing death. The judge stated that his concern was to deal only with the immediate and specific problem – that is, the administration of sustenance, which was ordered. However, he also said:

> *'… whatever may be the justification through some form of ethical assessment, for the adoption of a deliberate course of conduct designed to terminate the life of a child, the law in this community is clear and simple. It gives no warrant whatever for any such decision to be made. … Difficult problems … may be … involved in the preservation or continuation of life, but no parent, no doctor, no court, has any power to determine that the life of any child, however disabled that child may be, will be deliberately taken from it. … It does not permit decisions to be made concerning the quality of life, nor does it enable any assessment to be made as to the value of any human being'.*

Baby M

Although the Baby M case[11] was heard in the Victorian State Coroner's Court, whose findings did not at that time constitute law, nevertheless it suggested that a line of reasoning would be important in future cases before Australian courts. It concerned an infant born with a severe spina bifida with a large lumbar myelomeningocele, hydrocephalus, Arnold – Chiari malformation of the brain stem, vocal cord paresis and severe deformities of the lower limbs. She was relatively unresponsive, had little spontaneous movement and had difficulty swallowing, sucking and breathing. If surviving, she would unable to walk, be doubly incontinent, have no sexual function, probably require an artificial airway and would certainly require multiple operations on her spine and lower limbs. Her quality of future life was estimated extremely poor. Accordingly, the medical staff of the hospital and parents decided that no active treatment, including surgery to close the myelomeningocele, be undertaken. Feeding was restricted to that on demand and she was given paracetamol and phenobarbital. Subsequently, she developed respiratory difficulty, was treated with an infusion of morphine and died 12 days after birth. However, a member of the 'Right-to-Life' association complained to police about the infant's treatment. An autopsy was performed. The Deputy Coroner ruled that the infant had died of natural causes secondary to bronchopneumonia and hypoxia secondary to vocal cord paralysis obstructing the upper airway obstruction in the presence of toxic amounts of phenobarbital and morphine.

The case focused on the validity of withholding medical treatment in circumstances based on a *quality of life*. The Deputy Coroner, while noting that generally quality of life factors are not valid reasons to withhold treatment, the very serious disabilities of Baby M placed her in a group who would not be selected for surgery. Medical staff involved in the case was exonerated by the Deputy Coroner who stated that their decisions were legally, ethically and morally sound.

Baby D

This Victorian State case concerned Baby D,[12] who had been born at 27 weeks' gestation and required intubation and mechanical ventilation for apnoea of prematurity while a twin developed normally. Several extubation attempts were unsuccessful over several months due to development of tracheal stenosis. At one re-intubation, hypoxaemia caused cardiac arrest requiring external cardiac compression. A subsequent MRI scan revealed major hypoxic brain damage that was expected to result in severe cerebral palsy and blindness. However, she was conscious, had intact brainstem function and intact cardiorespiratory function except for life dependence on intubation. Her parents applied to the court to allow extubation (withdrawal of therapy) without re-intubation if airway obstruction re-occurred. The court sanctioned this withdrawal of therapy on the basis that continuation of life-maintaining treatment would result in a very poor quality of life, which was not in her best interests. The principle of 'double effect' of appropriate use of sedative agents to allay suffering but inevitably shortening life was also affirmed.

Re J

In this British case,[13] a 4-month-old infant was the subject of a medical recommendation to withhold mechanical ventilation. It was this case that introduced assessment of 'quality of life' as a touchstone.

The infant, asphyxiated and born prematurely at 27 weeks' gestation and weighing 1.1 kg, had required mechanical ventilation for 1 month initially and then recurrently over the course of the next 3 months. On one occasion he was resuscitated from pulselessness. At 3 months of age ultrasound studies revealed gross irreparable hypoxic brain damage. He was blind and neonatologists predicted that he would have spastic quadriplegia, deafness and be unlikely to develop even limited intellectual abilities. The judge ordered the hospital, in the infant's 'best interests', not to reventilate him.

On appeal it was argued that, as in Re C [1989] 2 All ER 782, court-sanctioned withholding of treatment applied to an infant who was dying or in whom death could only be postponed, whereas baby J was in no immediate danger. It was argued that a court is justified in withholding consent to such treatment only if it is certain that the quality of the child's subsequent life would be 'intolerable' to the child, 'bound to be full of pain and suffering' and 'demonstrably … so awful that in effect the child must be condemned to die' as per Judges Dunn and Templeman in Re B [1990] 3 All ER 927.

The court baulked at the terms 'condemned to die' and 'the child must live'. Although 'Thou shalt not kill' is an absolute commandment in this context it is permissible to add 'but need'st not strive officiously to keep alive'. A court can never sanction steps to terminate life and as Judge Taylor stated, 'The court was concerned only with the circumstances in which steps should not be taken to prolong life'. Thus, 'What doctors and the court have to decide is whether, in the best interests of the child patient, a particular decision as to medical treatment should be taken which as a side effect will render death more or less likely'. There is a 'balancing exercise' to be performed in assessing the course to be adopted in the best interests of the child. Accordingly:

> *'account has to be taken of the pain and suffering and quality of life which the child will experience if life is prolonged. … also … of pain and suffering involved in the proposed treatment itself. … I do not think that we are bound to, or should, treat (Judge) Templeman's use of the words 'demonstrably so awful' or Judge Dunn's use of the word 'intolerable' as providing a quasi-statutory yardstick. … there will be cases in which it is not in the interests of the child to subject it to treatment which will cause increased suffering and produce no commensurate benefit'.*

The issue before Lord Donaldson was whether it would be in the 'best interests' of the child to restart mechanical ventilation and subject him to all the associated processes of intensive care if at some future time he could not continue breathing unaided. In dismissing the appeal, his judgement strongly speaks to the issue of quality of life, and introduces an unacknowledged concept of futility as a basis for withholding treatment in appropriate circumstances.

Judge Taylor, concurring, also introduced a concept observed in American judgements: that of 'a substituted judgement':

> *'the correct approach is … to judge the quality of life the child would have to endure if given that treatment and decide whether in all circumstances such a life would be so afflicted as to be intolerable to that child. I say 'that child' because the test should not be whether the life would be tolerable to the decider. The test must be whether the child in question, if capable of exercising sound judgement, would consider the life intolerable'.*

The interpretation of the quality of life may be variable, depending on the circumstances of the patient, as illustrated by examples given by Judge Taylor in Re J. In a case of disability following an accident, as opposed to one of disability from birth, a perception by the child of what has been lost, rather than never known, may be relevant to judging the quality of life.

Re Wyatt

This is another English case[14] in which the parents of a severely disabled infant and doctors could not agree on treatment should the infant's condition deteriorate. It defined the role of a court order in subsequent medical management and re-examined the meaning of 'best interests'.

At the age of 1 year after birth at 26 weeks' gestation, this infant with microcephaly and profound brain damage was blind, deaf, incapable of voluntary movement or response and had severe spastic quadriplegia. In addition she had irreparable chronic lung damage necessitating permanent oxygen administration and had kidney dysfunction that would require dialysis. Following a dispute between the infant's parents and doctors, a court order was made that doctors could withhold mechanical ventilation otherwise necessary to prolong life, on the grounds that to do otherwise was not in the infant's best interests. Unexpectedly, mechanical ventilation was not needed. When the infant attained the age of 18 months, the parents applied to court to have the previous declaration discharged on the grounds that she was now not terminally ill. However, Judge Hedley declined to discharge the declaration after considering that her condition was unchanged. In doing so, he remarked on the utility of 'intolerability' as the test of best interests:

> *'it is in my view essential that the concept of "intolerable to that child" should not be seen as a gloss on, much less a supplementary test to, best interests. It is a valuable guide in the search for best interests in this kind of case'.*

The declaration was reviewed when the child was 2 years of age when again the concept of 'best interests' of the child was scrutinised. The court again

de-emphasised 'intolerability' as the touchstone of 'best interests' and reaffirmed its meaning as enunciated in Re A, that ' "best interests" encompasses medical, emotional and all other welfare issues' and that 'The court must conduct a balancing exercise in which all the relevant factors are weighed'. Notwithstanding, since any case will be highly specific: 'any criteria which seek to circumscribe the best interests tests are … to be avoided'. On this occasion, as on the previous, the Court declined to discharge the initial declaration but added that the declaration was permissive, not mandatory and subject to discussion between parents and doctors before implementation. It was not the court's role to oversee the treatment plan for a gravely ill child, which was for the doctors in consultation with the child's parents.

FUTILITY

Futility is difficult to define and it may be quite different according to the perspectives of parent and physician – as illustrated in In the matter of baby K[9] when doctors, opposed by the mother, sought to discontinue mechanical ventilation for an anencephalic infant solely on the basis of futility. Nevertheless, the concept has been drawn upon in an Australian case involving an adult but no children, and it has appeared in American and British cases involving adults and children.

Airedale NHS Trust v Bland

Withdrawal of treatment from persons in persistent vegetative status (PVS) came to legal notice in Britain in 1993 with Airedale NHS Trust v Bland.[15] Physicians of Anthony Bland, a young man in PVS after being asphyxiated in a crowd stampede, proposed cessation of artificial feeding and withholding of antibiotic therapy in case of infection. These actions would culminate in his death by starvation and, although unpleasant for hospital staff, would not cause discomfort or stress to the patient. His 'best interests' lay in being able to lawfully discontinue all life-sustaining treatment and medical support.

Lord Hoffmann considered that it is not just the interests of the patient that are being considered and reminded us of the American substituted judgment when he opined:

> *'in the extraordinary case of Anthony Bland, we think it more likely that he would choose to put an end to the humiliation of his being and the distress of his family. Finally, Anthony Bland is a person to whom respect is owed and we think that it would show greater respect to allow him to die and be mourned by his family than to keep him grotesquely alive'.*

Moreover, 'the decision does not involve … a decision that he may die because the court thinks that "his life is not worth living". There is no question being worth living or not worth living because the stark reality is that Anthony Bland is not living a life at all.'

Lord Mustill delivered comprehensive and clear statements related to the benefits to be gained by different parties. It was in the best interests of the community that Anthony Bland be allowed die:

> *'it is the best interests of the community at large that Anthony Bland's life should now end. …. Nothing will be gained by going on and much will be lost. The stress of the family will get steadily worse. The strain on the devotion of a medical staff charged with the care of a patient whose condition will never improve, who may live for years and who does not even recognise that he is being cared for, will continue to mount. The large resources of skill, labour and money now being devoted to Anthony Bland might in the opinion of many be more fruitfully employed in improving the condition of other patients, who if treated may have useful, healthy and enjoyable lives for many years to come.'*

In addition, according to Lord Mustill, it would be in best interests of his family that he die, and therefore in his own best interest to die:

> *'He suffers no pain and feels no mental anguish … and (he experiences) the progressive erosion of the family's happy recollections by month after month of distressing and hopeless care'. 'By ending his life the doctors will not relieve him of a burden become intolerable, for others carry the burden and he has none … he has no interests of any kind'.*

The invasiveness of treatment, the indignity and its futility should be in the best interests of the family not to experience:

> *'account should be taken of the invasiveness of the treatment and the indignity to which, as the present case shows, a person has to be subjected if his life is prolonged by artificial means, which must cause considerable distress to the family – a distress which reflects not only their own feelings but their perception of the situation of their relative who is being kept alive. But in the end it is the futility of the treatment which justifies its termination' [emphasis added].*

Messiha v South East Health

This Australian case involved a 75-year-old man in deep coma with absent cortical activity several days after sustaining an hypoxic–ischaemic injury during asystolic cardiac arrest secondary to heart and lung disease.[16] Physicians proposed withdrawing mechanical ventilation, which would culminate in his death earlier than if treatment was continued. This was opposed by family members. A judge ruled that withdrawal of treatment was permitted on the grounds of futility:

> *'Apart from extending the patient's life for some relatively brief period, the current treatment is futile … burdensome and … intrusive. The withdrawal of treatment may put his life in jeopardy but only to the extent of bringing forward what I believe to be the inevitable*

in the short term. I am not satisfied that the withdrawal of his present treatment is not in the patient's best interests and welfare'.

Re L

Dame Elizabeth Butler-Sloss stressed that 'best interests' was the appropriate test and also clarified the role of futility and 'intolerability' in paediatric cases. The issue concerned a 9-month-old infant with trisomy 18 who had multiple heart defects, chronic respiratory failure, gastroesophageal reflux, severe developmental delay, epilepsy and hypotonia, and who had already suffered cardiac and respiratory arrests.[17] In supporting the judgement of Judge Hedley in Wyatt, she remarked:

'There is a strong presumption in favour of preserving life, but not where treatment would be futile, and there is no obligation on the medical profession to give treatment which would be futile. I agree with (Judge) Hedley that the court should be focusing on best interests rather than the concept of intolerability, although the latter may be encompassed within the former'.

Re L.H.R.

Futility as noted above is sometimes difficult to define but it was done clearly in this American case in which the parents of a 4-month-old infant wanted unwilling doctors and a hospital to withdraw treatment.[18] The infant had suffered a 'medical catastrophe' 15 days after birth and had since been in a persistent vegetative state. A State Supreme Court, acknowledging that the infant never had an opportunity to develop and express ideas and was terminally and hopelessly ill with no reasonable possibility of ever attaining cognitive function, pronounced 'Under these circumstances, we find that the *life-support system was prolonging her death rather than her life*' (emphasis added). The author of this chapter has found this concept useful in explaining to relatives of patients the meaning of 'futility'.

BURDENS VERSUS BENEFITS

Sometimes determination of the 'best interests' is a matter of weighing the burdens and benefits.

This was described clearly by the judgement in In the matter of AB[19] in which an American court ruled that, upon a request from a mother, treatment could be withdrawn from her 3½-year-old child who had sustained hypoxic brain damage secondary to a cardiac arrhythmia. The decision hinged on the 'best interest' standard, which 'requires a weighing of the benefits and burdens of treatment options including non-treatment as objectively as possible. Factors that should be considered when making decisions about life-sustaining or life-saving treatments for a seriously ill newborn include: (1) the chance the therapy will succeed, (2) the risks involved with treatment and non-treatment, (3) the degree to which the therapy if successful will extend life, (4) the pain and discomfort associated with the therapy and (5) the anticipated quality of life with and without treatment'.

Benefit vs burden was also the issue in the British case of An NHS Trust v B[20] – a case in which doctors wanted to withdraw mechanical ventilation, against the wishes of parents, from an 18-month-old child who had spinal muscular atrophy type I. The child's illness had progressed to the point where the only spontaneous movement possible was that of eyebrows. The case is notable for three reasons. The first is that the court drew up an extensive list of burdens and benefits specific to the child that serve as a good illustration of factors needing consideration in an individual case. Secondly, although the burdens appeared to heavily outweigh the benefits and hence favour discontinuation of treatment, Judge Holman ruled in favour of continuing mechanical ventilation via endotracheal intubation. Thirdly, as the judge also ruled against the need for a tracheostomy, this created a difference between withdrawing treatment (cessation of mechanical ventilation) and withholding treatment (tracheostomy).

Mohammed's Case

This astounding decision attracted considerable media attention in Britain. The decision is not in agreement with a previous case of a 16-month-old ventilated child with SMA type I, Re C,[21] in which the judicial decision was to allow the withholding of mechanical ventilation against parental wishes in the event of a future respiratory arrest once the present mechanical ventilation had been successively weaned. The decision is also not in agreement with a subsequent case – Re K,[22] in which the court ruled that it was appropriate to cease parenteral nutrition and to allow die a 5½-month-old infant with congenital myotonic dystrophy who had required mechanical ventilation for intermittent episodes of septicaemia associated with central venous access. The judge distinguished the circumstances from those in An NHS Trust v B on the basis of age and development.

The recent Australian case of TS & DS v Sydney Children's Hospital Network ("Mohammed's case")[23] was adjudicated on the basis of a preponderance of burden over benefit in determining a child's best interests. Parents demanded invasive mechanical ventilation for their 9-month-old infant with a severe neurodevelopmental disorder due to pyruvate dehydrogenase deficiency. Their infant, after a prolonged period of hypoxaemia, was unresponsiveness, had seizures, blindness, deafness and cardiac failure requiring continuous positive airway pressure. Doctors advised against ventilation on the basis that the infant's condition was incurable. The court ruled that ventilation would cause pain and discomfort, would provide only temporary benefit and would not alleviate his underlying condition. Rather, his best interests were to receive pain relief and palliative care.

CLINICAL GUIDELINES ON WITHHOLDING AND WITHDRAWING TREATMENT

The withholding and withdrawal of life-sustaining treatment are the subjects of numerous guidelines.

Most relevant are those of the Royal College of Paediatrics and Child Health (RCPCH), those of the American Academy of Paediatrics and those of the General Medical Council (GMC).

RCPCH GUIDELINES

The RCPCH guidelines,[24] last published in 2004, claim to take into account recent changes in legislation and legal cases. They identify five situations where it is ethical and legal to withhold or withdraw life-sustaining treatment: the 'brain-dead' child, the 'permanent vegetative state', the 'no chance' situation, the 'no purpose situation' and the 'unbearable situation'. However, these divisions are somewhat confused. The state of 'brain death' requires no legal or ethical decision as it is, but not merely, a question of when to stop treatment depending upon the acceptance by and reasonable wishes of parents and any considerations of organ donation. Although both "no purpose" situation and the "unbearable" situations may be the basis for withholding or withdrawal of treatment, the "no purpose" situation is also described, confusingly, in terms of the child being unreasonably expected to "bear the situation". All categories are said to be determined by the 'child's best interests' yet heavy reliance is placed on the concept of 'intolerability', which has drawn strong judicial criticism in Re Wyatt,[14] R (Burke) v General Medical Council [2005] EWHC 1879 and in Re L.[17]

A guiding principle of the ethical framework is claimed to be adherence to legal duty, but which is curiously described as 'arguably inconsistent' – a term that is neither expounded nor justified. The legal basis is Re J (A Minor)(Wardship: Medical Treatment) [1990] 3 All ER 930: 'when the quality of life the child would have to endure if given the treatment would be so afflicted as to be *intolerable* to the child'. The guidelines declare that a number of legal judgements (but does not identify them) have established that there is no obligation to give treatment which is futile and burdensome, that feeding and other medical treatment may be withdrawn in patients in whom the vegetative state is thought to be permanent, and that treatment may be withdrawn from patients if continuation is not in their best interests. Although these statements may be true, the legal details are absent.

Nevertheless, these ethical principles have been lauded in common law cases such as An NHS Trust v B [2006] but, as expected, judges are always keen to point out that they do not constitute law.

AMERICAN ACADEMY OF PEDIATRICS GUIDELINES[25]

These are similar those of the RCPCH but use the term 'forgo' to refer to both stopping (withdrawing) treatment already begun and not starting (withholding) a treatment, and decisions turn on the 'best interests' standard. This involves balancing the benefits and burdens of treatment. Benefits may include prolongation of life (unless prolonged unconsciousness is not considered a benefit), improved quality of life after treatment (including reduction of pain or disability) and increased physical pleasure, emotional enjoyment and intellectual satisfaction. The burdens of treatment include intractable pain, irremediable disability or helplessness, emotional suffering, invasive or inhumane interventions designed to sustain life or other activities that detract from the patient's quality of life.

'Quality of life' refers to that perceived by the patient, not how others perceive it. Accordingly, a 'substituted judgement standard' should apply in which parents or surrogates must make inferences about the preferences of previously competent children. However, in states of prolonged unconsciousness, this standard cannot be applied easily.

Curiously, despite exhortation to regard quality of life only from the patient's perspective, 'Physicians and families should also consider whether continued treatment conforms with respect for the meaning of human life and accords with the interests of others, such as family members and other loved ones'.

GENERAL MEDICAL COUNCIL GUIDELINES[26]

These extensive ethical statements include references to common-law cases, legislation (limited) and to the European Convention on Human Rights.

The essential concepts are the doctor's ethical obligation to show respect for human life, to protect the patient's health and to make patient's best interests their first concern. This means offering those treatments where possible benefit outweighs any burdens and risks associated with the treatment, and avoiding those treatments where there is no net benefit to the patient.

Benefits and burdens are not limited to purely medical considerations. Doctors should not simply substitute, for the incompetent patient, their own values or those of people consulted. Prolonging life will usually be in the best interest of the patient, provided it is not excessively burdensome or disproportionate in relation to expected benefits. Not continuing or not starting a potentially life-prolonging treatment is in the best interests of the patient when it would provide no net benefit.

When death is drawing near, doctors should not strive to prolong the dying process with no regard to the patient's wishes, where known, or to current assessment of the benefits and burdens of treatment and non-treatment.

Where patients lack capacity, an assessment of the benefits, burdens and risks, and the acceptability of proposed treatment must be made on their behalf by the doctor, taking account of the patient's wishes, if known. Where these are unknown, it is the doctor's responsibility to decide what is in the patient's best interests after consulting those close to the patient.

The guideline contains a section of legal background including the following:

- Life-prolonging treatment may be lawfully withheld or withdrawn from incompetent patients when commencing or continuing treatment is not in their best interests (Airedale NHS Trust v Bland [1993] 1 All ER 821).
- There is no obligation to give treatment that is futile and burdensome (Re J (A Minor)(Wardship: Medical Treatment) [1990] 3 All ER 930).
- For children or adults who lack capacity, in reaching a view on whether a particular treatment would be more burdensome than beneficial, assessments of the likely quality of life for the patient with or without the particular treatment may be one of the appropriate considerations (Re B [1981] 1 WLR; Re C (A Minor) [1989] All ER 782; Re J (A Minor)(Wardship: Medical Treatment) [1990] 3 All ER 930; Re R (Adult: Medical Treatment) [1996] 2 FLR 99).
- In the case of patients in a permanent vegetative state, artificial nutrition and hydration constitute medical treatment and may be lawfully withdrawn (Airedale NHS Trust v Bland [1993] 1 All ER 821).
- Final responsibility rests with the doctor to decide what treatments are clinically indicated and should be provided to the patient, subject to a competent patient's consent or, in the case of an incompetent patient, any known views of that patient prior to becoming incapacitated and taking account of the views offered by those close to the patient (Re J (A Minor)(Child in Care: Medical Treatment) [1992] 2 All ER 614; Re G (Persistent Vegetative State) [1995] 2 FCR 46).
- The Human Rights Act 1998 has implications by incorporating into English law the European Convention on Human Rights. Relevant to withholding and withdrawing life-prolonging treatment are Article 2, which requires that life be protected, Article 3, which prohibits inhuman and degrading treatment, and Article 8, which requires respect for private and family life. It is noted that case law is consistent with the Convention.

These guidelines are arguably the best since recommendations are clearly based on legal decisions and, moreover, have been approved by the Court of Appeal (R v General Medical Council [2005] EWCA Civ 1003). However, prior to this judgement they had not escaped legal criticism (Burke v GMC [2004] 3 FCR 579), principally because they failed to acknowledge the incompetent person's wishes, stated when competent, for provision of treatment particularly of life-sustaining nutrition and hydration. Moreover, it was maintained that withdrawal of treatment contrary to advance direction was in breach of the European Convention on Human Rights and required judicial authorisation.

The GMC appealed the decision claiming that the judge had erred in relation to a patient's right to demand treatment, and in the use of an excessively narrow scope of 'intolerability' as the touchstone of the patient's best interests. The Appeal Court, reversing the lower court's ruling, held that a competent patient could not demand treatment that a doctor considered adverse to the patient's needs, and held that a doctor was not required to keep alive a patient who while competent had expressed a wish in an advance directive to be maintained alive when entering a persistent vegetative state. Furthermore, the test of 'best interests' of an incompetent patient was to be determined by the individual's circumstances, of which 'intolerability' was but one. The Appeal Court also held that, although there would be circumstances in which it would be advisable for a doctor to seek a court's approval before withdrawing artificial nutrition and hydration from a patient not in a persistent vegetative state, there was no legal duty to do so.

Far from being critical of the GMC's guidelines, the Appeal Court lent support to the guidelines and expressed its wish that the GMC promulgate, teach and implement their guidelines in every hospital.

CONCLUSIONS

In considering whether to withhold or withdraw life-sustaining treatment from a child, the appropriate test is that of 'best interests', which although a nebulous term essentially means

> *a determination of the quality of life, futility and a comparison of benefits and burdens.*

These three concepts are not independent as 'quality of life' with continuation of treatment may be derived by a 'comparison of benefits and burdens' flowing from treatment. 'Best interests' should also incorporate, but not exclusively, a notion of tolerability of continued treatment. The concept of futility was prominent in early cases and remains important but it is less easily defined unless related to prolongation of the dying process. These legal concepts may be helpful in the clinical situation when litigation is unlikely, but when parties nevertheless dispute courses of action each of which is considered correct under different ethical positions. It may be surprising to physicians that these principles are well described in law. Indeed, rather than consider withdrawal or withholding treatment under ethical principles, it perhaps more helpful to first ask 'Is it lawful?' and then ask 'Is it ethical?'. Whatever ethical position is adopted when contemplating withholding or withdrawing treatment from children, notwithstanding disputes, these principles should be observed because, in the end, the legal position is decisive.

Paediatric poisoning

James Tibballs

EPIDEMIOLOGY

The peak incidence of poisoning in childhood is among 1–4-year-olds. It usually occurs in the home when the child ingests a single prescribed or over-the-counter medication or a household product. Approximately 3500 young children are admitted to hospital each year in Australia.[1] This mode of poisoning is called 'accidental' – erroneously, because it is usually the result of inadequate supervision or unsafe storage of poisons. The mortality is very low and if hospitalisation is required, it is usually brief (1–3 days), so care must be taken to ensure that whatever treatment is applied, it does not cause additional illness.

Occasionally, poisoning in childhood is either truly accidental as in ingestion of a decanted chemical, or is part of a syndrome of child abuse, or is iatrogenic as when a parent mistakes medications at home or when medical or nursing staff make errors in drug administration in hospital. Unfortunately, medication errors occur with approximately 5% of paediatric inpatient medication.[2] Self-poisoning in older children is usually with the intention to manipulate their psychosocial environment or to commit suicide, or is the result of substance abuse. All such circumstances of poisoning require remedial action. Occasionally toxic gases are inhaled for example during fires.

PRINCIPLES OF MANAGEMENT

The four basic principles in management of poisoning are:

- support vital functions
- confirm the diagnosis
- remove the poison from the body
- administer an antidote[3,4] (**Table 112.1**).

Individual poisons may require specific measures. Consult current toxicology texts[5–7] for details and consult Chapter 88. Knowledge of important poisons is indispensable for paediatric practice. A number of poisons or classes of poison are potentially fatal to a small child if taken as a single tablet or a teaspoonful.[8] These include opiates (methadone, buprenorphine, lomotil), camphor, quinine derivatives, cyclic antidepressants, clonidine, sulfonylureas, salicylates, calcium channel blockers and colchicine. If a poison is unfamiliar, a poison information centre provides valuable information but clinical judgement rests with the physician.

The support of paediatric vital functions (life-support) is detailed in Chapters 103–105, 108–111 and 113 of this volume.

CONFIRMATION OF DIAGNOSIS

Commonly, the diagnosis of poisoning in paediatric practice is self-evident from a history detailed by parents or guardians. Although a single poison is usually involved, the possibility of several or multiple poisons should be considered. Occasionally the diagnosis is unknown on presentation. Any child who presents with unexplained obtundation, fitting, hypoventilation, hypotension or has a metabolic derangement must have the diagnosis excluded.

Recognition of a 'toxidrome', a constellation of symptoms and signs, may make the diagnosis.[5–7] Although numerous toxidromes exist, the four prominent types and their causative drugs or agents are shown in **Table 112.2**.

Laboratory analysis of body fluid specimens can assist in diagnosis and management of poisoning. For example, rapid routine analyses are widely available for glucose, potassium, calcium, pH, osmolarity, alcohols, paracetamol, phenytoin, digoxin, salicylate, theophylline, iron, lead, and methaemoglobin. If particular toxins are suspected, discussion with laboratory staff will optimize information to be gained.

REMOVAL OF THE POISON

Treatment should be determined by the poison, severity of poisoning as judged by the observed and expected effects of the poison, by the amount ingested, by the interval between ingestion and presentation and by the existence or otherwise of an antidote.

The range of treatment options is to: do nothing apart from advice and discharge home, observe for a short duration in the emergency department or ward, provide intensive nursing care, or treat medically. The modes of medical therapy include extracorporeal

Table 112.1 Antidotes to some poisons

POISON	ANTIDOTES	COMMENTS
Amphetamines	Esmolol i.v. 500 µg/kg over 1 min, then 25–200 µg/kg per min Labetalol i.v. 0.15–0.3 mg/kg or phentolamine i.v. 0.05–0.1 mg/kg every 10 minutes	Treatment for tachyarrhythmia Treatment for hypertension
Anticholinergic toxidrome (antimuscarinic)	Physostigmine 0.01–0.02 mg/kg i.v. slowly, repeatable but titrated to improve consciousness	Beware cholinergic effects including bradycardia, bronchospasm and weakness (treat with atropine)
Benzodiazepines	Flumazenil i.v. 3–10 µg/kg, repeat 1 minute, then 3–10 µg/kg per hour	Specific receptor antagonist. Beware convulsions
Beta blockers	Glucagon i.v. 50–150 µg/kg repeat after 3–5 min, then infusion of effective dose/h Isoproterenol i.v. 0.05–3 µg/kg per min Norepinephrine i.v. 0.05–1 µg/kg per min	Stimulates non-catecholamine cAMP (preferred antidote) Beware β_2 hypotension Antagonises toxin at receptors
Calcium channel blocker	Calcium chloride i.v. 10%, 0.2 mL/kg	Antagonises at receptors
Carbon monoxide	Oxygen 100%	Decreases carboxyhaemoglobin May need hyperbaric oxygen
Cyanide	Dicobalt edetate i.v. 4–7.5 mg/kg Hydroxocobalamin (vitamin B12) i.v. 70 mg/kg Amyl nitrite 0.2 mL perles by inhalation until sodium nitrite 3% i.v. 0.13–0.33 mL/kg over 4 min, then sodium thiosulphate 25% i.v. 1.65 mL/kg (max 50 mL) at 3–5 minutes	Give 50 mL 50% glucose after dose 'Cyanide antidote kit'; beware anaphylaxis, hypertension Beware hypotension; nitrites form methaemoglobin–cyanide (beware excess methaemoglobin >20%); thiosulphate forms non-toxic thiocyanate from methaemoglobin–cyanide
Digoxin	Magnesium sulphate i.v. 25–50 mg/kg (0.1–0.2 mmol/kg) Digoxin Fab i.v: acute – 10 vials per 25 tablets (0.25 mg each), 10 vials per 5 mg elixir; steady state: vials, serum digoxin (ng/mL) ×BW(kg)/100; empirical therapy: 10–20 vials acute poisoning, 1–2 vials chronic	Antagonises digoxin at sarcolemma Binds digoxin
Ergotamine	Sodium nitroprusside infusion 0.5–5.0 µg/kg per min Heparin i.v. 100 units/kg, then 10–30 units/kg per hour	Treats vasoconstriction; monitor BP continuously Monitor partial thromboplastin time
Lead	Dimercaprol (BAL) i.m. 75 mg/m^2 4-hourly, six doses, then i.v. $CaNa_2$ edetate (EDTA) 1500 mg/m^2 over 5 days or oral succimer (DMSA, dimercaptosuccinic acid) 350 mg/m^2 8-hourly (or 30 mg/kg/day) for 5 days, then 12-hourly 14 days if blood level >3.38 µmol/L; if asymptomatic and blood level 2.65–3.3 µmol/L, infuse $CaNa_2$EDTA 1000 mg/m^2 per day 5 days or oral succimer (DMSA, dimercaptosuccinic acid) 350 mg/m^2 8-hourly (or 30 mg/kg/day) for 5 days	Chelating agents

Continued

Table 112.1 Antidotes to some poisons—cont'd

POISON	ANTIDOTES	COMMENTS
Heparin	Protamine 1 mg/100 units heparin	Direct neutralisation
Hydrofluoric acid	Calcium chloride 10% i.v. 0.2 mL/kg Calcium gluconate gel, topically	For systemic toxicity For burns
Iron	Deferoxamine 15 mg/kg per hour 12–24 hours if serum iron >90 µmol/L (500 µg/dL) or >63 µmol/L (350 µg/dL) and symptomatic, give slowly	Beware anaphylaxis
Isoniazid (or hydrazine exposure)	Pyridoxine (vitamin B6) 70 mg/kg (max 5 g) i.v. 3–5 minutes if seizing, 30–60 minutes if not, *and* Diazepam	Metabolic acidosis may be mildly exacerbated
Local anaesthetic drug cardiovascular toxicity	Intralipid 20% i.v. 1.5 mL/kg over 1 min, repeat ×2 intervals 5 min then infusion 0.25–0.50 mL/kg/min as needed to maintain BP	Mechanism uncertain – may bind toxin; suitable for other lipophilic drugs including sertraline, bupropion, quetiapine and possibly clomipramine, propranolol, thiopentone, verapamil
Methanol, ethylene glycol, glycol ethers	Ethanol i.v. loading dose 10 mL/kg 10% diluted in glucose 5%, then 0.15 mL/kg per hour to maintain blood level 0.1% (100 mg/dL), *or* Fomepizole (4-methylpyrazole) 15 mg/kg over 30 minutes, then 10 mg/kg 12-hourly, four doses	Competes with poison for alcohol dehydrogenase Inhibits alcohol dehydrogenase (not available in Australia)
Methaemoglobinaemia	Methylene blue i.v. 1–2 mg/kg over several minutes	Reduces methaemoglobin to haemoglobin
Methotrexate	Leucovorin (folinic acid) i.v. 100–1000 mg/m^2 6-hourly until methotrexate 0.05–0.1µmol/L, *and* Glucarpidase 50 units/kg i.v.	Sustains folate cycle blocked by methotrexate Cleaves methotrexate to non-cytotoxic metabolites
Opiates	Naloxone i.v. 0.01–0.1 mg/kg, then 0.01 mg/kg per hour as needed	Direct receptor antagonist
Organophosphates and carbamates	Atropine i.v. 20–50 µg/kg every 15 minutes until secretions dry Pralidoxime i.v. 25 mg/kg over 15–30 minutes then 10–20 mg/kg per hour for 18 hours or more	Blocks muscarinic effects Reactivates cholinesterase; not for carbamates
Paracetamol	*N*-acetylcysteine i.v. 150 mg/kg in dextrose 5% over 1 hour, then 50 mg/kg per hour for 4 hours then 100 mg/kg for 16 hours (total 300 mg/kg over 20 hours), *or* oral 140 mg/kg, then 17 doses of 70 mg/kg 4-hourly (total 1330 mg/kg over 72 hours), if serum paracetamol exceeds 1500 µmol/L at 2 hours, 1000 at 4 hours, 500 at 8 hours, 200 at 12 hours, 80 at 16 hours, 40 at 20 hours	Restores glutathione-inhibiting metabolites; beware anaphylaxis
Phenothiazine (and other drug) dystonia	Benzatropine i.v or i.m. 0.01–0.03 mg/kg	Blocks dopamine reuptake

Table 112.1 Antidotes to some poisons—cont'd

POISON	ANTIDOTES	COMMENTS
Potassium	Calcium chloride 10% i.v. 0.2 mL/kg Glucose i.v. 0.5 g/kg plus insulin i.v. 0.05 units/kg Salbutamol aerosol 0.25 mg/kg Sodium bicarbonate i.v. 1 mmol/kg Resonium oral or rectal 0.5–1 g/kg	Antagonises cardiac effects (immediate) Decreases serum potassium (rapid marked effect); monitor serum glucose Decreases serum potassium (rapid marked effect) Decreases serum potassium (slight effect); beware hypocalcaemia Adsorbs potassium (slow effect)
Sulfonylureas and other drugs causing hypoglycaemia	Glucose 0.5–1.0 g/kg i.v. then infusion Octreotide 1–2 μg/kg 8-hourly	Monitor serum glucose frequently Refractory hypoglycaemia from sulfonylureas and quinine; inhibits insulin release
Tricyclic antidepressants	Sodium bicarbonate i.v. 1–2 mmol/kg to maintain blood pH >7.45, aim for 7.55	Reduces cardiotoxicity
Valproic acid	L-carnitine i.v. if serum valproate ≥450 mg/L, no coma and ammonia and liver enzymes normal: 25 mg/kg 6-hourly (max 6 g/day); if coma with raised ammonia and hepatic enzymes 100 mg/kg load (max 6 g) over 30 min then 15 mg/kg 4-hourly over 10–30 min until improvement	Replaces depleted carnitine levels; measure valproate – if ≥1000 mg/L start haemodialysis or haemoperfusion

decontamination, diuresis or gastrointestinal decontamination, with the last-named of most importance. The task with all poisonings is to match the treatment and its intensity to the severity of the poisoning, thereby avoiding under- and overtreatment.

EXTRACORPOREAL DECONTAMINATION

Occasionally, removal from the circulation by an extracorporeal technique is needed by charcoal haemoperfusion, haemodialysis, plasma filtration or haemofiltration. Examples of toxins removable by these techniques are barbiturates, lithium, metformin, salicylates, theophylline, toxic alcohols, carbamazepine and valproic acid.[3,9] Such techniques, combined with extracorporeal circulatory support, should be applied when conventional therapy is failing or is anticipated to fail.

ALKALINE DIURESIS

Induce diuresis of 2–5 mL/kg/h with alkalinisation of the urine by 1–2 mmol/kg sodium bicarbonate i.v. then infuse 50–75 mmol/L in intravenous fluid titrated to maintain alkaline urinary pH without exceeding serum pH of 7.55. Monitor serum pH, sodium, potassium, calcium and avoid clinical problems of fluid overload. This reduces reabsorption in distal renal tubules of drugs including phenobarbitone, salicylate, methotrexate, and chlorpropamide.[3]

GASTROINTESTINAL DECONTAMINATION

Since the vast majority of poisoning in childhood is by ingestion, potential exists for removal from the gastrointestinal tract before absorption. However, the correct choice and timing of a gastrointestinal decontamination technique are crucial to uncomplicated recovery. The usual choices are activated charcoal, induced emesis, gastric lavage, whole bowel irrigation, or a combination of these techniques. Occasionally endoscopic removal may be needed. The efficacy, indications, contraindications and disadvantages and complications of these techniques are discussed below. A general plan of management is presented in **Figure 112.1**.

A crucial point in management is initial recognition that the patient is in a state of either 'full-consciousness' or 'less-than-full consciousness'. Traditionally, management has been dependent on a judgement of whether the gag reflex is present or absent, but in practice this is rarely tested. Since aspiration pneumonitis is a common feature of poisoning management, particularly among (but not confined to) obtunded patients, it is prudent to regard all obtunded patients as having incompetent pharyngeal reflexes.

The decision to attempt removal of a poison should always be made with due reference to two facts:

- The vast majority of childhood poisonings recover with merely supportive care or no treatment at all.
- Aspiration pneumonitis is more serious than most poisonings.

Table 112.2 Toxidromes

TOXIDROME	SIGNS AND SYMPTOMS			DRUGS/AGENTS (EXAMPLES)
Anticholinergic	Agitation Coma Delirium Mydriasis Dry mouth Hyperthermia Tachycardia (sinus) Hypertension Skin flushed and dry Urinary retention Ileus or decreased motility			Antihistamines Atropine and related drugs and substances (inc. plants) Carbamazepine Phenothiazines Tricyclic antidepressants Benzatropine
Cholinergic	MUSCARINIC	NICOTINIC	CENTRAL	
	Diarrhoea Urinary incontinence Miosis Bradycardia Bronchorrhoea Vomiting Lacrimation Salivation	Weakness/paralysis Fasciculation Tachycardia Hypertension	Obtundation/coma Agitation Seizures	Organophosphates Carbamates
Sympathomimetic	Agitation Delirium/coma Seizures Mydriasis Hyperthermia Sweating Hypertension Tachycardia Hyperpnoea			Amphetamines and derivatives Cocaine Caffeine Catecholamines Ketamine Phenylcyclidine Theophylline Lysergic acid diethylamide
Opioid/opiate	Obtundation/coma Hypoventilation Hypotension Miosis			Morphine Heroin Methadone Fentanyl Oxycodone Buprenorphine Propoxyphene

ACTIVATED CHARCOAL

Charcoal adsorbs many drugs and is regarded as a 'universal antidote'.[3,10] Although advocated as sole treatment in most poisonings, it is overused for minor poisonings and for many poisons no data exist regarding efficacy.

Treatment of charcoal with chemicals and heat increases its surface area to approximately 950 m^2/g in so-called low-surface-area activated charcoal and to 2000 m^2/g in superactivated charcoal. The latter adsorbs paracetamol better and is more palatable.[11,12] Activated charcoal is not pleasant to drink and is associated with vomiting in 20% of poisoned children.[13] It is superior to induced emesis and gastric lavage in treatment of symptomatic poisoned patients,[14–16] but its efficacy diminishes with time after ingestion. Activated charcoal reduces absorption of ingested experimental drugs in volunteers by 85–100% when administered 5 minutes after ingestion,[17–19] by 40–75% at 30 minutes[20] and by 30–50% at 60 minutes.[19,21] At mean times of 98 minutes[22] or more than 2 hours[23] after poisoning, it was not effective at all.

Activated charcoal alone is as effective as when combined with either emesis or with lavage,[24] but in combination with these methods has an 8.5% incidence of aspiration, compared with zero when used alone.[18]

Repeated doses of activated charcoal (multi-dose) enhance elimination of some drugs by increased adsorption and by post-absorption elimination by

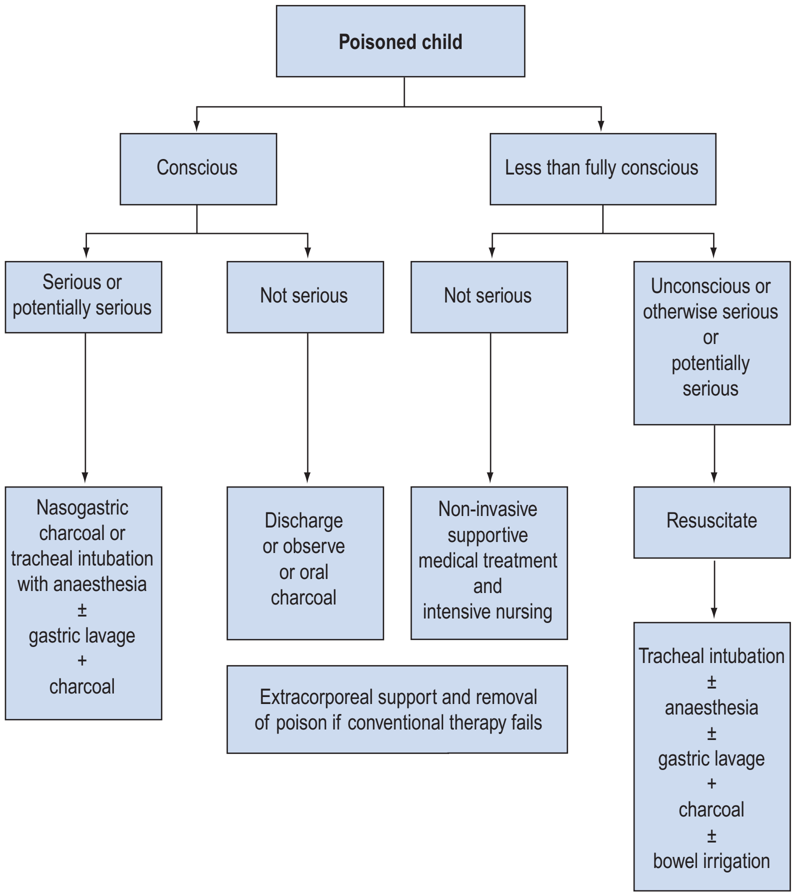

Figure 112.1 General management of the poisoned child.

interruption of an enterohepatic circulation and by removing drug from the gastrointestinal mucosa ('gastrointestinal dialysis'). Although multiple reports exist in experimental and clinical practice (**Box 112.1**),[25] there is no hard evidence to show that this therapy reduces mortality or morbidity. Only in life-threatening poisoning by carbamazepine, dapsone, phenobarbital, quinine or theophylline should multiple-dose activated charcoal be considered.[25]

A suitable single dose is 1–2 g/kg. A multiple-dose regimen for children is 1–2 g/kg stat followed by 0.25–0.5 g/kg 4–6-hourly. An alternative is 0.25–0.5 g/kg hourly for 12–24 hours.[26]

Contraindications

- Ileus
- A less-than-fully-conscious patient unless already intubated
- Substances not adsorbed – for example, strong corrosive acids and alkalis, cyanide, metals (iron, lithium, mercury, lead), alcohols, glycols, petroleum distillates (not all) and essential oils[5–7]

Complications

Aspiration of charcoal causes severe and often fatal pneumonitis, bronchiolitis obliterans and adult respiratory distress syndrome. Inadvertent intratracheal instillation of activated charcoal causes a significant increase in lung microvascular permeability and arterial blood gas derangements.[27]

Constipation is common after charcoal, but bowel obstruction is fortunately rare. The addition of a laxative (e.g. sorbitol or magnesium sulphate) is not recommended because, although transit time through the gut is decreased, efficacy of the charcoal is reduced and life-threatening fluid and electrolyte imbalance may occur.[28]

INDUCED EMESIS

For many reasons, induced emesis with ipecacuanha (ipecac) has disappeared from hospital practice and should not be performed routinely in this setting.[29] Ipecac contains alkaloids, mainly emetine and cephaeline, that induce emesis by stimulation of the chemoreceptor trigger zone of the medulla and by irritation of the gastric mucosa.

Box 112.1 Elimination and lack of elimination of drugs by multiple-dose activated charcoal[25]

Elimination increased in experimental and clinical studies	Elimination increased in volunteer studies	Elimination not increased in experimental or clinical studies
Carbamazepine	Amitriptyline	Astemizole
Dapsone	Dextropropoxyphene	Chlorpropamide
Phenobarbital	Digitoxin	Doxepin
Quinine	Digoxin	Imipramine
Theophylline	Disopyramide	Meprobamate
	Nadolol	Methotrexate
	Phenylbutazone	Phenytoin
	Phenytoin	Sodium valproate
	Piroxicam	Tobramycin
	Sotalol	Vancomycin

The efficacy of ipecacuanha (ipecac) is limited and decreases with time from ingestion. Although it causes vomiting in a high percentage (93–100%) of children within 25 minutes, the percentage of stomach contents ejected is small (28%) even when administered immediately after ingestion.[30] Moreover, solids are retained in the stomach or may even be propelled into the duodenum.[20] In adults, ipecac is even less useful and has to be given immediately to have quantifiable effects.[31]

It does not improve outcome and may reduce effectiveness of the alternative treatments of activated charcoal, oral antidotes and whole bowel irrigation. However, its use in the home is safe and is associated with fewer paediatric emergency department attendances,[32] and it is still recommended by authoritative paediatric health organisations in the USA.[33] Although ipecac was recommended inappropriately in 20% of cases reported to poisons information centres, it caused little morbidity.[34]

Experimentally, approximately 50–83% of ingested experimental drug is removed if ipecac is given after 5 minutes,[17] falling to 2–44% if given at 30 or 60 minutes.[21,35–38] In paediatric paracetamol poisoning, the 4-hour post-ingestion serum level was approximately 50% of controls if ipecac-induced vomiting occurred within 60 minutes of ingestion, but no benefit was derived if emesis occurred beyond 90 minutes after ingestion.[39] Similarly, serum levels of paracetamol were reduced approximately 50% if ipecac was administered at home, inducing emesis at a mean of 26 minutes after ingestion, compared with ipecac administered at a medical facility at a mean of 83 minutes.[40]

Critics claim that induced emesis merely creates work, delays discharge from the emergency department[41] increases complications[41] and does not benefit the patient who presents more than 1 hour after ingestion.[42] Importantly, ipecac did not alter the clinical outcome of patients who presented awake and alert to the emergency department.[15]

Induced emesis appears superior to gastric lavage but inferior to activated charcoal. In salicylate poisoning, emesis retrieved twice as much as gastric lavage.[43] In adult volunteers ipecac-induced vomiting, occurring at an average of 19 minutes after ingestion, removed 54% of a tracer compared with 30% with gastric lavage performed at the equivalent times after ingestion.[14,44,45]

Contraindications

Specific contraindications include actual or impending loss of full consciousness or ingestion of corrosives or hydrocarbons.[29]

Complications

Potential complications include time-related lack of efficacy, protracted vomiting (17%), diarrhoea (13%) and lethargy (12%).[46] More serious, but rare, complications include gastric, oesophageal or brain haemorrhage, pneumomediastinum, aspiration pneumonitis, which may occur even in the fully conscious patient, delayed onset of vomiting, which is a threat if loss of consciousness subsequently occurs, and abuse in bulimia, which may cause cardiotoxicity as well as the sequelae associated with repetitive vomiting.

In hospital, induced emesis has no practical role. Even when a child presents very early after significant poisoning, oral or nasogastric charcoal is preferred. Importantly, whenever induced emesis is used the child must be fully conscious on administration and is expected to be fully conscious when vomiting occurs.

GASTRIC LAVAGE

The place of this in the management of the poisoned victim is very limited.[47] It is invasive, ineffective and potentially harmful. It should be reserved for the child who presents very soon after a life-threatening ingestion such as iron.

It involves passage of a large-bore oro- or nasogastric tube into the stomach and the repeated instillation of fluid, usually water, but some authorities advocate normal or half-normal saline. The oral route is preferred because of less potential for traumatic injury but an oropharyngeal airway may be needed to prevent tube occlusion by chomping. A smaller tube may be used if the poison is a liquid. Traditionally, the child should be placed in the left lateral position to limit stomach emptying, but volume of intragastric contents rather than body position determines gastric emptying.[48]

Experimental studies on liquids indicate that gastric lavage retrieves 90% at 5 minutes,[49] 45% at 10 minutes[45] and 30% at 19 minutes[44] and reduces absorption or bioavailability by 20–32% at 1 hour after ingestion.[35,50] When performed 5 minutes after ingestion of tablet drugs, it failed to prevent absorption, presumably because the tablets had not disintegrated.[18] In true

overdose situations, gastric lavage within 4 hours of admission reduced serum paracetamol levels by 39%.[51]

Efficacy of gastric lavage, even with large-bore tubes, is poor because tablets are not removed and lavage encourages propulsion into the duodenum.[30] In symptomatic patients, gastric lavage alone compared with gastric lavage and activated charcoal increased pneumonic aspiration and did not alter the duration of intubation or the stay in the emergency department or the intensive care unit (ICU),[16] and was not beneficial unless performed within 1 hour of ingestion.[15] An RCT of gastric lavage in acute overdose[24] (criticised methodologically),[24,52] suggested that it made no difference to outcome of obtunded patients when preceding activated charcoal.

Contraindications

- Less-than-fully conscious patient (unless already intubated) because of the risk of aspiration pneumonitis – which is not negligible even during full consciousness[16]
- After ingestion of corrosives because of the risk of perforation
- After ingestion of hydrocarbons or petrochemicals because of the risk of pneumonitis.

Complications

- Aspiration pneumonitis
- Water intoxication
- Minor trauma to oropharynx (gastro-oesophageal perforation occurs rarely)
- Intrabronchial instillation of lavage fluid.

As expected, infants and children never cooperate fully for gastric lavage, thus increasing risks of complications and the degree of psychological trauma.

If lavage is indicated (i.e. for life-threatening poisoning), rapid sequence induction of anaesthesia with intubation is mandatory. The largest possible lubricated tube of diameter similar to an appropriate-sized endotracheal tube should be used and correct placement in the stomach confirmed. Small volumes (1–2 mL/kg) of warm tap water or 0.9% saline may be used to lavage until clear. However, most fluids should be retrieved to avoid complications with fluid and electrolytes, particularly hyponatraemia if water is used.

WHOLE BOWEL IRRIGATION

Irrigation of the bowel with an iso-osmolar solution of polyethylene glycol and electrolytes is effective in reducing absorption of experimental drug by 24–67% at 1 hour after ingestion[53,54] and up to 73% at 4 hours after ingestion.[55] However, it is not conclusively proven to improve the outcome. The technique has limited applications to sustained-release or enteric-coated drugs and remains a theoretical option for ingestions of iron, lead, zinc (substances not adsorbed by activated charcoal), packets of illicit drugs[56] and for lithium.[57] Whole bowel irrigation may be useful in delayed presentations when poisons have progressed beyond the stomach.

Since irrigation solutions are adsorbed by activated charcoal and cause desorption of drug, this necessitates prior administration of charcoal if a combined technique is used.[58] However, whole bowel irrigation did not add to the benefits of activated charcoal in an experimental model of sustained-release theophylline poisoning.[59]

A suitable regimen is approximately 30 mL/kg per hour for 4–8 hours until rectal effluent is clear. A regimen of 25 mL/kg per hour has been used safely for 5 days (total 44.3 litres),[60] but a total of 3 litres was as effective as 8 litres in a simulated poisoning.[61]

Contraindications

Risk of aspiration during:

- less-than-full consciousness
- bowel obstruction or ileus.

PLAN OF MANAGEMENT

A general plan of management is suggested in Figure 112.1, but each case of poisoning mandates a specific management according to circumstances: consciousness and risk of aspiration, timing of presentation in relation to the severity of poisoning and the existence or otherwise of an effective antidote dictate if removal should be attempted, and by what means.

POISONING BY SPECIFIC SUBSTANCES

Like adults, children are poisoned regularly by therapeutic prescription or over-the-counter therapeutic drugs and substances (see Ch. 88). The poisons probably reflect their availability in the home. In a survey, the most common agents responsible for hospital admission of children were benzodiazepines, anticonvulsants, antiparkinsonism drugs, paracetamol, major tranquillisers, antidepressants and cardiovascular drugs.[62] The inquisitive nature of young children results in poisoning by substances not normally regarded as dangerous and not encountered in adults. A few of these are considered here briefly.

BUTTON OR DISC BATTERIES

Ingestion may cause electrolytic injury and potentially corrosive, toxic or pressure injury. There are many types of batteries that contain a variety of substances; the most important are lithium, mercury and potassium hydroxide.

Impaction in the oesophagus is the most significant situation; this can result in oesophageal perforation and tracheo-oesophageal fistula or aorto-oesophageal fistula. An impacted battery must be removed endoscopically as soon as possible. Lithium batteries are large and impact readily and they have higher voltages

than other types. Electrolysis commences as soon as the battery surfaces are immersed in oesophageal fluid. The consequence is local and surrounding tissue destruction, including the trachea.[63] Strong alkali is produced at the cathode and strong acid is produced at the anode. Mercury batteries are more likely to fragment[64] but mercury poisoning is very uncommon.

Sufficient follow-up is necessary to exclude oesophageal and tracheal damage and to ensure that a battery in the stomach or distal bowel is eliminated.

PETROLEUM DISTILLATES

Numerous by-products of petroleum distillation are utilised for industrial and domestic purposes. Ingestion of these hydrocarbons may cause CNS toxicity (comprising obtundation and convulsion), gastrointestinal irritation, occasional hepatorenal toxicity, and pneumonitis.

Pneumonitis is the most significant and it may occur during ingestion or subsequent vomiting. Although variable, these substances have low surface tensions, which enables their rapid dispersement throughout contiguous mucosal surfaces including the respiratory tree. Prime examples are petrol, kerosene, lighter fluid, lamp oil and mineral spirits. Any child who ingests a distillate must be assessed for pneumonitis and this should include clinical examination, a chest X-ray and at least a non-invasive measurement of oxygenation such as pulse oximetry. Although most children who ingest petroleum distillates do not develop pneumonitis, the onset of this complication may be within 30 minutes[65] and progress rapidly to severe lung disease. An adequate period of observation (6 hours) is necessary to exclude this complication. There is a poor correlation between the amount ingested and the severity of pulmonary toxicity.

Deliberate inhalation of volatile hydrocarbons such as petrol or aerosolised paint has the additional toxicity on myocardial tissue, including fatal tachydysrhythmia, possibly due to sensitisation to endogenous catecholamines. The deliberate inhalation of paint fumes, usually via a plastic bag, is known as 'chroming'.

ESSENTIAL OILS

The oils from certain plants contain mixtures of terpenes, alcohols, aldehydes, ketones and esters, which are used domestically for various purposes. The well-known oils are eucalyptus, turpentine, citronella, cloves, tea tree, peppermint, wintergreen and lavender. In general, small amounts cause depression of conscious state, irritation of gastrointestinal tract, liver dysfunction and pneumonitis if inhaled. Each has different toxicity. For example, as little as 5 mL of eucalyptus oil[66] or 15 mL of turpentine may cause depression of conscious state.

Emesis should not be induced and gastric lavage performed only if airway protection is required.

LEAD

Children are more susceptible to lead poisoning after ingestion than are adults, possibly because of better absorption.

Acute poisoning usually occurs after ingestion of a lead salt or metallic foreign body or a lead-containing product, such as paint, traditional remedy or cosmetic. Acute poisoning by a salt may cause life-threatening cardiovascular collapse and encephalopathy.

Chronic poisoning can occur with ingestion of lead-contaminated water, or by inhalation of leaded petrol fumes or contaminated house dust. Chronic poisoning causes multi-organ dysfunction including neuromuscular dysfunction and encephalopathy.

Treatment consists of gastric decontamination in the case of recent ingestion of lead salts. The use of intravenous or oral chelating agents may be indicated.[67] In the case of ingestion of a lead foreign body, serial X-rays should be taken to ensure elimination, otherwise surgical removal is indicated. In the case of multiple embedded gunshot pellets and in all cases of chronic poisoning, serum lead levels should be measured to guide chelation therapy (see Table 112.1).

PARACETAMOL

This is the most common drug ingested by children in an accidental, iatrogenic or deliberate overdose situation. Overdose has the potential for hepatic failure and, less commonly, renal failure. The onset of toxicity is delayed – up to several days. Consequently, the need for acute gastric decontamination is uncommon, but would be justifiable for acute large-dose presentations. The toxicity in part is caused by the hepatic metabolite of the drug (*N*-acetyl-*p*-benzoquinoneimine), which accumulates when endogenous glutathione, which facilitates conversion of *N*-acetyl-*p*-benzoquinoneimine to non-toxic substances, becomes exhausted. Adequate supply of glutathione is ensured by administration of the antidote *N*-acetylcysteine, a glutathione precursor that can be administered intravenously or orally (see Table 112.1).

Time of presentation after ingestion, as well as dose, determines management. If presentation is within 1 hour of ingestion, effective gastric removal or administration of activated charcoal may be all that is required pending a serum paracetamol level. In contrast, if presentation is several hours after ingestion, administration of the antidote according to serum paracetamol level takes precedence and, although it may be administered orally or intravenously, the intravenous route is generally preferred.[68] In one study, hepatic toxicity was slightly less in patients treated with the intravenous regimen compared with the oral regimen in patients whose treatment was initiated within 12 hours of ingestion, but later than 18 hours hepatic toxicity was slightly less in patients treated with the oral regimen compared with the intravenous regimen, with no difference in

toxicity in those treated with either regimen at presentations between 12 and 18 hours after ingestion.[69]

Near-simultaneous administration of activated charcoal and acetylcysteine may be of some benefit but it may also cause vomiting or desorption, thus decreasing the effectiveness of the oral antidote. If presentation is many hours after the poisoning, activated charcoal is not indicated, so the antidote could be administered orally if necessary according to serum paracetamol levels. In all cases, evidence of liver dysfunction mandates administration of the antidote.

The threshold single toxic dose of paracetamol indicating *N*-acetylcysteine administration is generally regarded as 150 mg/kg, although it has been suggested that a single dose less than 200 mg/kg in children less than 6 years of age may be safely managed at home.[70] However, in situations of repeated sub-150 mg/kg doses hepatotoxicity has a high mortality among children[71] and in adults.[72] Unfortunately, toxic overdosing by chronic administration is not uncommon even in paediatric institutions.[73]

No sufficient data exist on which to firmly base a decision when to administer *N*-acetylcysteine to children. In lieu of this, time-related serum levels of paracetamol should be measured and reference made to a guideline to administer the antidote (see Table 112.1) as derived from single toxic dose adult data.[74] The serum paracetamol level indicating antidote has been predicted as >225 mg/L (1500 μmol/L) at 2 hours after ingestion of a single overdose of elixir in children 1–5 years of age.[22] If serum levels of paracetamol cannot be obtained and >150 mg/kg has been ingested as a single dose, or liver dysfunction is present after chronic poisoning, the antidote should be given.

Adverse reactions to *N*-acetylcysteine (approximately 7–8%) respond to an antihistamine[75] and its temporary cessation.

IRON

Small quantities of elemental iron (>20 mg/kg) are toxic to children. This dose may be reached by ingestion of a few iron tablets. The initial effects are gastrointestinal, which may include gastric erosion, followed sometimes by an interval before cardiovascular failure occurs at 6–24 hours and then followed by multi-organ failure (including encephalopathy) and hepatic and renal failure up to some 48 hours after ingestion. In addition to general supportive measures, specific management should include abdominal X-ray to determine if unabsorbed tablets are present, in which case gastric lavage or whole bowel irrigation may be useful. Activated charcoal is useless. Chelation therapy with deferoxamine (see Table 112.1) should be guided by serum iron level and clinical status.

CAUSTIC SUBSTANCES

In a study of 743 children,[76] the incidence of oesophageal burns caused by ingestion of automatic machine dishwashing detergents was 59%, caustic soda 55% and drain cleaners 55%. All are strongly alkaline and are corrosive. Dishwasher detergents are presented as liquids, powders or tablet blocks and are commonly accessed in an open dishwasher.[77] Pharyngeal and oesophageal irritation, burns or corrosion may occur. There may be simultaneous ocular and dermal toxicity. Any child presenting with a history of ingestion of a caustic substance, irrespective of clinical signs, should be considered for oesophagoscopy and follow-up since the correlation between symptoms and signs and oesophageal burns is poor[76] and significant oesophageal damage may occur in the absence of more proximal injury.[78]

Paediatric cardiopulmonary resuscitation

James Tibballs

Basic and advanced cardiopulmonary resuscitation (CPR) for infants and children are described. The essentials of resuscitation are presented in figures for the infant and child (**Fig. 113.1**) and for the newly born infant (**Fig. 113.2**). Recommendations are based on guidelines published by resuscitation organisations[1–3] that are derived from evaluation of the science of resuscitation by the International Liaison Committee on Resuscitation.[4]

This chapter is focused on medical and nursing personnel in hospital and complements Chapters 21 (Adult cardiopulmonary resuscitation) and 103 (The critically ill child). To add ability to knowledge, it is advisable to undertake a specialised paediatric cardiopulmonary resuscitation course, such as the Advanced Paediatric Life Support (APLS) or Paediatric Advanced Life Support (PALS) courses.

Distinctions within the term 'paediatric' are based on combinations of physiology, physical size and age. Some aspects of CPR are different for the 'newly born', infant, small (younger) child and large (older) child:

- *'newly born'* (newborn): the infant at birth or within several hours of birth
- *'infant'*: an infant outside the 'newly born' period and up to the age of 12 months
- *'small/young child'*: a child of preschool and early primary school from the age of 1–8 years
- *'large/older child'*: a child of late primary school from the age of 9 up to 14 years
- children older than 14 years may be treated as adults, but they do not have the same propensity for ventricular fibrillation as do adults.

EPIDEMIOLOGY

The causes of cardiopulmonary arrest (CPA) in infants and children are many and include any cause of hypoxaemia or hypotension, or both. Common causes are trauma (motor vehicle accidents, near-drowning, falls, burns, gunshot), drug overdose and poisoning, respiratory illness (asthma, upper-airway obstruction, parenchymal diseases), postoperative (especially cardiac), septicaemia and sudden infant death syndrome. As many as 10% of newly born infants require some form of resuscitation for varied conditions of which birth asphyxia is the most common.

PREVENTION

Cardiopulmonary arrest occurring in hospital may be preventable. Every institution which admits children should have a system to recognise deterioration, call for assistance and to provide rapid enhancement of the level of care, hence the use of medical emergency teams, rapid response teams and paediatric early warning scores.[5]

BASIC LIFE SUPPORT

ASSESSMENT OF AIRWAY AND BREATHING

If the child is not responsive to tactile and auditory stimulation, not breathing normally and not moving, the rescuer should assess the airway and breathing, which can be achieved in either the supine or lateral position. Obvious causes of airway obstruction in the pharynx should be removed. Fluids such as vomitus or blood should be aspirated with a Yankauer sucker. Solid or semi-solid objects such as food particles or foreign objects should be removed with an instrument (e.g. Magill's forceps). Since the most common cause of airway obstruction in an obtunded state is the tongue, first-aid manoeuvres to elevate it should be performed. These manoeuvres are backward head tilt, chin lift and jaw thrust. Head tilt and chin lift are often combined. If neck injury is present or suspected, neither the head tilt nor the chin lift manoeuvre should be used. Following establishment of an airway, the presence or absence of adequate breathing is assessed by inspection of movement of the chest and abdomen, and by listening and feeling for escape of exhaled air from the mouth and nose (look, listen and feel). If adequate breathing is occurring the patient should be placed on the side in a coma position.

RESCUE BREATHING (EXPIRED AIR RESUSCITATION)

If breathing is inadequate then expired air resuscitation or bag-(valve)-mask ventilation should be commenced

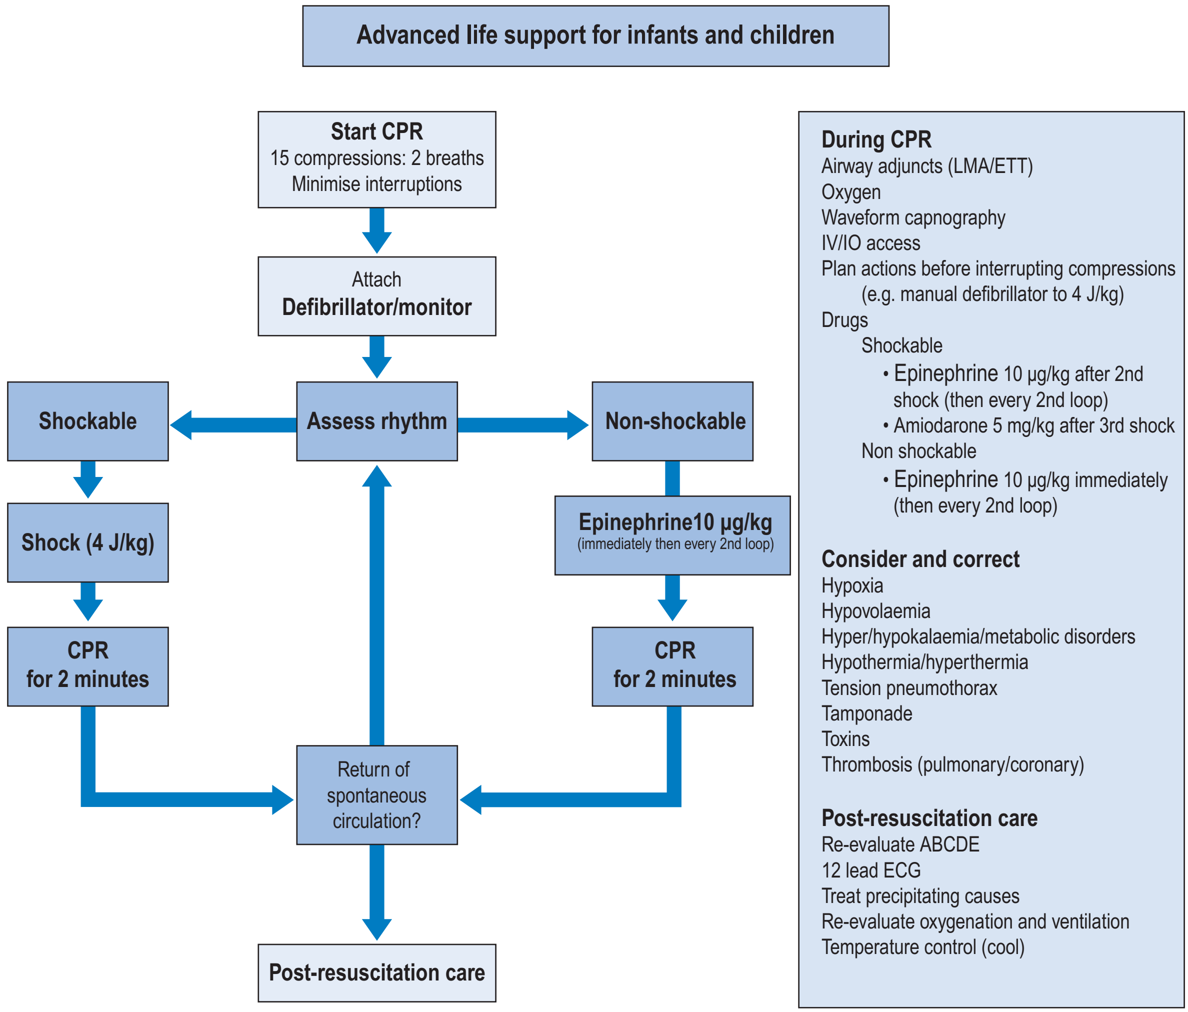

Figure 113.1 Advanced life support for infants and children. PEA=pulseless electrical activity; VF=ventricular fibrillation; VT=ventricular tachycardia. *(Reproduced with permission from the Australian Resuscitation Council, Melbourne.)*

immediately. Initially at least two breaths are recommended, but some guidelines suggest up to five. (There is no definitive evidence.) While maintaining the airway, administer slow breaths over 1–1.5 seconds to achieve adequate chest inflation. In children of all sizes, a mouth-to-mouth technique is possible by pinching the nostrils closed. In the newly born and infants, a mouth-to-mouth-and-nose technique is recommended, but if the rescuer has a small mouth then a mouth-to-nose technique is an alternative. Lack of chest rise may signify obstruction of the airway requiring repositioning of the head and neck.

ASSESSMENT OF CIRCULATION

If the child is unresponsive and not breathing, external cardiac compression (ECC) should be commenced immediately. Pulse by palpation may be performed, but the 'pulse check' has been removed from CPR guidelines for lay-persons because of their inability to reliably check the pulse, which may also be an issue for healthcare personnel. Palpation of any major pulse (carotid, brachial, femoral) is appropriate. If a pulse cannot be detected within 10 seconds or the rate is inadequate (<60 beats/min) then external cardiac compression (ECC) should be commenced.

EXTERNAL CARDIAC COMPRESSION (ECC)

Different techniques are used for infants and children of different sizes but in all patients the depth of compression is one-third the depth of their chest. For newly born infants and infants, two techniques are in common use. In the 'two-finger technique', the middle finger and forefinger are used. This technique is taught to lay-persons and is also the preferred technique for a single healthcare rescuer. With the better 'two-thumb technique', the hands encircle the thorax, approaching the

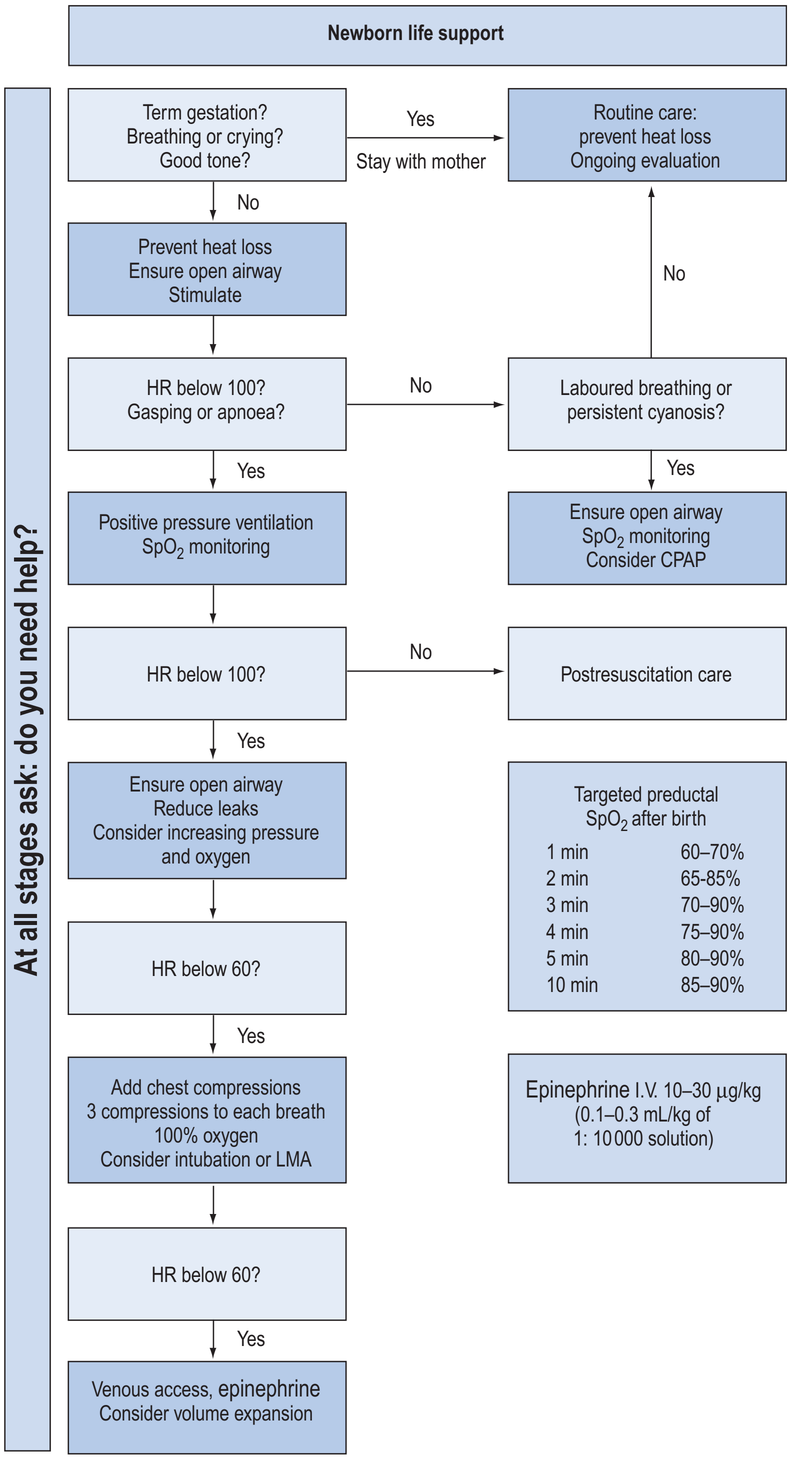

Figure 113.2 Newly born infant resuscitation. *(Reproduced with permission from the Australian Resuscitation Council, Melbourne.)*

chest from either above or below, and the thumbs are placed either opposite, alongside or atop one another. With this technique, the rescuer must take care to avoid restriction of the patient's chest during inflation. With premature newly born and small infants, the rescuer's encircling fingers may reach and stabilise the vertebral column without limiting chest inflation. With both techniques, the sternum is compressed above the xiphoid or about one fingerbreadth below the internipple line.

Either a single hand or both hands may be used for infants and children as determined by the relationship between the size of the patient's chest and the hands of the rescuer. For young children, ECC can be performed with the heel of one hand. For older children, a bimanual technique as per adults may be used. In all ages, the 'centre of the chest' – which corresponds to the lower sternum – is compressed. Approximately 50% of each cycle should be compression. Every effort should be made to minimise 'hands-off' time (interruptions). This requires coordinated teamwork when, for example, ECC is paused to allow rhythm analysis or the application of DC shock.

RATES OF COMPRESSION AND RATIO OF COMPRESSION TO VENTILATION

In hospitals (two or more rescuers), the ratio of compression to ventilation for infants and children should be 15:2. Resuscitation may be commenced with either ventilations or compressions. After every 15 compressions, a pause should allow delivery of two ventilations whenever expired air resuscitation or any type of mask ventilation is given. ECC can be given during the second exhalation. The aim should be to achieve about 5 cycles per minute (i.e. about 75 compressions and 10 breaths per minute). If circulation returns, but respiration remains inadequate, the number of ventilations should be higher but care should be taken to avoid hypocarbia, which results in cerebral ischaemia. A sole healthcare rescuer may use the lay-person ratio of 30:2, aiming to achieve about 5 cycles in 2 minutes (i.e. about 75 compressions and 5 breaths per minute).

For infants and children, compressions should be delivered at a rate of 100/min (i.e. 1 compression every 0.6 seconds or approximately 2 per second). As ventilation is interposed between compressions, the actual compressions delivered will be less than 100 each minute. If the airway has been secured (e.g. by endotracheal intubation), strict coordination of compression and ventilation is not crucial; ventilation can be given against resistance imposed by chest compression. In this case about 100 compressions/minute will be achieved, but ventilation should be limited to about 10–12 per minute and wherever possible guided by arterial blood gas analysis. This low rate is all that is needed to match low cardiac output achieved during ECC. Excessive ventilation detracts from effectiveness of ECC and causes hypocarbia.

For newly born infants the total number of recommended 'events' per minute is 120, with the aim of achieving 90 compressions and 30 inflations each minute (i.e. in a ratio of 3:1). Beyond the newly born period (i.e. when the lungs have been inflated), the compression–ventilation ratio of 15:2 should be used.

ADVANCED LIFE SUPPORT

As soon as practicable, mechanical ventilation with added oxygen should be commenced with either a bag-mask or via endotracheal intubation. Although intubation is preferred (see below), valuable time should not be wasted in numerous unsuccessful attempts. Initial effective bag-mask ventilation is sufficient and necessary prerequisite for successful paediatric CPR. Bags of appropriate sizes should be available for infants, small children and large children. A bag of ~500 mL volume should be available for newly born infants. Insertion of an oropharyngeal (Guedel) airway may be necessary to facilitate bag-mask ventilation. Access to the circulation and display of the electrocardiograph and oximetry should also be achieved as soon as possible. Thereafter treatment should be guided by the cardiac rhythm. Underlying causes of CPA should be sought and treated.

AIRWAY MANAGEMENT

If attending personnel are skilled, the trachea should be intubated as soon as practicable. This establishes and maintains an airway, facilitates mechanical ventilation with 100% oxygen, minimises the risk of pulmonary aspiration, enables suctioning of the trachea and provides a route for the administration of selected drugs. If difficulty is experienced at initial intubation, oxygenation should be established with bag-mask ventilation before a re-attempt at intubation. Initial intubation should be via the oral route (not nasal), because oral intubation is invariably quicker than nasal, is less likely to cause trauma and haemorrhage, and enables the endotracheal tube to be more easily exchanged if the first choice is inappropriate. On the other hand, a tube placed nasally can be better affixed to the face and so is less likely to enter a bronchus or be subject to inadvertent extubation, and is preferred for transport and long-term management. A nasogastric tube should be inserted after intubation to relieve possible gaseous distension of the stomach sustained during bag-mask ventilation.

Correct placement of the endotracheal tube in the trachea must be confirmed. In the hurried conditions of emergency intubation at cardiopulmonary arrest, it is not difficult to mistakenly intubate the oesophagus or to intubate a bronchus. There is no substitute for:

- visualising the passage of the tip of the endotracheal tube through the vocal cords at intubation

- confirmation of bilateral pulmonary air entry by auscultation in the axillae
- continuous observation of bilateral rise and fall of the chest on ventilation
- observation of the patient becoming and remaining pink.

Immediately after intubation, tracheal placement of the tube should be confirmed by capnography or colorimetric CO_2 detection. The former is preferred because it also affords ongoing assessment of adequacy of ECC and ventilation as well as a continuous warning of accidental extubation. Excretion of CO_2 needs effective pulmonary blood flow and ventilation of the lungs. Failure to detect CO_2 while there is either spontaneous or ECC-generated cardiac output necessitates immediate exclusion of oesophageal intubation by direct laryngoscopic inspection. If the tube is correctly located in the trachea, and CO_2 is not detected or is low, ECC should be improved and hyperventilation, if occurring, limited. Oxygenation should be confirmed with use of a pulse oximeter or measurement of arterial gas tension.

Uncuffed tube sizes (internal diameter)

- 2.5 mm tube for a premature newborn <1 kg; 3.0 mm for infants 2.0–3.0 kg; 3.0 or 3.5 mm for infants >3.0 kg and up to age 6 months; 4 mm for infants 7 months to 1 year
- for children over 1 year, the size is approximately determined by the formula: size (mm) = age (years)/4 + 4.

Cuffed tube sizes (internal diameter)

- 3.0 mm for newborns ≥3 kg and ≤1 year; 3.5 mm for children 1–2 years
- for children over 2 years, the size is approximately determined by the formula: size (mm) = age (years)/4 + 3.5

Larger and smaller tubes should be available. The correct size should allow a small leak on application of moderate pressure but also ensure adequate pulmonary inflation. Cuffed tubes have the advantage of avoiding a change when deemed too small in a hazardous situation but occupy more volume in a small airway.

The tube is inserted a specific depth to avoid accidental extubation and endobronchial intubation, both of which may threaten oxygenation. Assessment of the depth of insertion at laryngoscopy is not reliable because this is performed with the neck extended and when the laryngoscope is removed the head assumes a position of neutrality or flexion with the depth of insertion increasing automatically. Whether oral or nasal intubation, on a chest X-ray taken with the head in neutral position, the tip of the tube should be at the interclavicular line. If not, its depth should be adjusted.

Appropriate initial depths of insertion measured from the centre of the lips for an oral tube are:

- 9.5 cm for a term newly born; 11.5 cm for a 6-month-old; 12 cm for a 1-year-old
- after 1 year of age the depth is given by the formula: depth (cm) = age (years)/2 + 12.

Appropriate initial depths of insertion measured at the nares for a nasal tube are:

- 11–11.5 cm for a term newly born; 13 cm for a 6-month-old; 14 cm for a 1-year-old
- after 1 year of age the depth is given by the formula: depth (cm) = age (years)/2 + 15.

Laryngeal mask airways (LMA) may be used to establish and maintain an airway in the spontaneously breathing patient and for emergency relief of upper airway obstruction, but they have a limited role during CPR. Their role in provision of mechanical ventilation remains uncertain. Like bag-mask ventilation, they do not protect the airway from aspiration. Although insertion of an LMA is easier to learn than endotracheal intubation, training should not replace mastery of bag-mask ventilation. An LMA is not suitable for long-term use or during transport when endotracheal intubation is preferred. Sizes are available to suit body weight (kg) of newborns, infants and children: <5 kg size 1, 5–10 kg size 1½, 10–20 kg size 2, 20–30 kg size 2½, 30–50 kg size 3, 50–70 kg size 4, 70–100 kg size 5, and >100 kg size 6.

ELECTROCARDIOGRAPH

The electrocardiograph (ECG) should be displayed with either leads or paddles. Drug therapy or immediate direct current (DC) shock is determined by the existing rhythm.

ACCESS TO THE CIRCULATION

Access to the circulation via a peripheral or central vein should be attempted immediately (depending on skill). Any site is acceptable. Visible or palpable peripheral veins are to be found on the dorsum of the hand, wrist, forearm, cubital fossa, chest wall, foot and ankle. In infants, scalp veins are accessible and the umbilical vein can be used up to about 1 week after birth. Although the external jugulars are usually distended and easily cannulated at CPR, this may be impeded by performance of intubation or bag-mask ventilation. Cannulation of femoral, subclavian or internal jugular veins is an option, but difficult and hazardous in this situation. Surgical cutdown onto a long saphenous, saphenofemoral junction or basilic vein is a valuable skill sometimes required in traumatic exsanguination. Any pre-existing functioning line can be used provided it does not contain any drug or electrolyte precipitating the CPA.

INTRAOSSEOUS INJECTION

If intravenous (i.v.) access cannot be achieved rapidly (within 60 seconds), intraosseous (i.o.) access should be

obtained. This route has been used for patients of all ages and provides rapid, safe and reliable access to the circulation. It serves as an adequate route for any parenteral drug and fluid administration.

A metal needle with a trocar (e.g. disposable intraosseous needle; Cook, Illinois, USA) is preferable. Although many sites have been used for bone marrow injection, the easiest to identify is the anteromedial surface of the upper or lower tibia, especially in children less than 6 years. The site of the former is a few centimetres below the anterior tuberosity and the latter a few centimetres above the medial malleolus. The handle of the device needle is held in the palm of the hand while the fingers grip the shaft about a centimetre from the tip. It is inserted perpendicular to the bone surface and a rotary action is used to traverse the cortex. Sudden loss of resistance signifies entry to bone marrow. Correct positioning of the needle is confirmed by aspiration of bone marrow (which may be used for biochemical and haematological purposes) but that is not always possible. Bone injection guns (e.g. Wais Med Ltd), which propel a needle to a preset depth or drills (e.g. EZ-IO, Mayo Healthcare), enable easy intraosseous injection for infants, children and adults. The latter devices are preferred.

Volume expanders need to be given by syringe to achieve rapid restoration of circulating volume and rapid access of drugs to the central circulation. This is best achieved using a 10 mL syringe with a three-way tap in the i.v. tubing so that the i.o. needle does not become dislodged inadvertently.

Care should be exercised to avoid complications, particularly cutaneous extravasation, compartment syndrome of the leg and osteomyelitis. Contraindications include local trauma and infection.

ENDOTRACHEAL ADMINISTRATION OF DRUGS

Lipid-soluble drugs – epinephrine (adrenaline), atropine, lidocaine and naloxone – may be administered via the endotracheal tube if neither i.v. nor i.o. access is possible. Although the optimal doses of these drugs by this route are not known, work in animal models suggests doses should be 10 times the i.v. doses. The drugs should be diluted in normal saline up to 2 mL for infants, 5 mL for small children and 10 mL for large children. It is acceptable and simplest to squirt the drugs from the syringe (after removing the needle) directly into the endotracheal tube and disperse them throughout the respiratory tree with bagging. Neither sodium bicarbonate nor calcium salts should be administered via the tracheal route because they injure the airways.

DC SHOCK

Defibrillators should have paediatric paddles of cross-sectional area 12–20 cm^2 for use in children <10 kg body weight. For others, adult-sized paddles (50–80 cm^2) are satisfactory provided the paddles do not contact each other. Selectable energy levels should enable delivery of doses 0.5–4 J/kg. The closest level to the dose should be selected. One paddle is placed over the mid-axilla opposite the xiphoid or nipple, and the other to the right of the upper sternum below the clavicle. Conductive gel (confined to the area beneath the paddles) or gel pads and firm pressure are needed to deliver optimum energy to the heart without causing skin burns. The doses for monophasic and biphasic shock are the same.

In the treatment of refractory arrhythmias, equipment failure should be excluded. An anteroposterior position of the paddles (one over the cardiac apex, one over the left scapula) may be efficacious in refractory arrhythmia. Dextrocardia may be present with congenital heart disease and the position of the paddles should be altered accordingly.

Monophasic and biphasic automated external defibrillators (AEDs) with attenuated energy doses (approximately 50 J or less) may be used for children 1–8 years of age (approximately 10–25 kg). Adult energy doses of 150–200 J may be used in children older than 8 years of age or 25 kg body weight. Although AEDs are not recommended for use in infants as they may not reliably distinguish ventricular fibrillation from tachycardia and hence pose a risk of harmful DC shock, in the situation of a 'shockable' rhythm with poor or no cardiac output, an AED with dose attenuation may be used. If that is not available, an adult AED may be used.

Rescuers should be cognisant of the risk of inadvertent shock to themselves and colleagues during operation of defibrillators. They should ensure that they have no physical contact with the patient directly or indirectly at the time of electrical discharge. Surgical gloves provide minimal protection against shock. Paddles should be charged only when already placed on the chest of the patient. If the need to give DC shock abates while the paddles are charged, they should be disarmed before replacing them in their cradles.

TREATMENT OF SPECIFIC ARRHYTHMIAS

The following discussion of specific arrhythmias assumes that mechanical ventilation with oxygen and external cardiac compression has been commenced. The treatment of pulseless arrhythmias is summarised in **Figure 113.3**. Reversible causes of arrhythmias should be sought and treated during resuscitation. For example:

- *hypoxaemia or hypotension causing bradycardia*: may respond to ventilation
- *hypocalcaemia and toxicity caused by calcium channel blockade:* may be treated with calcium i.v. or i.o. (chloride 10% 0.2 mL/kg, gluconate 10% 0.7 mL/kg)

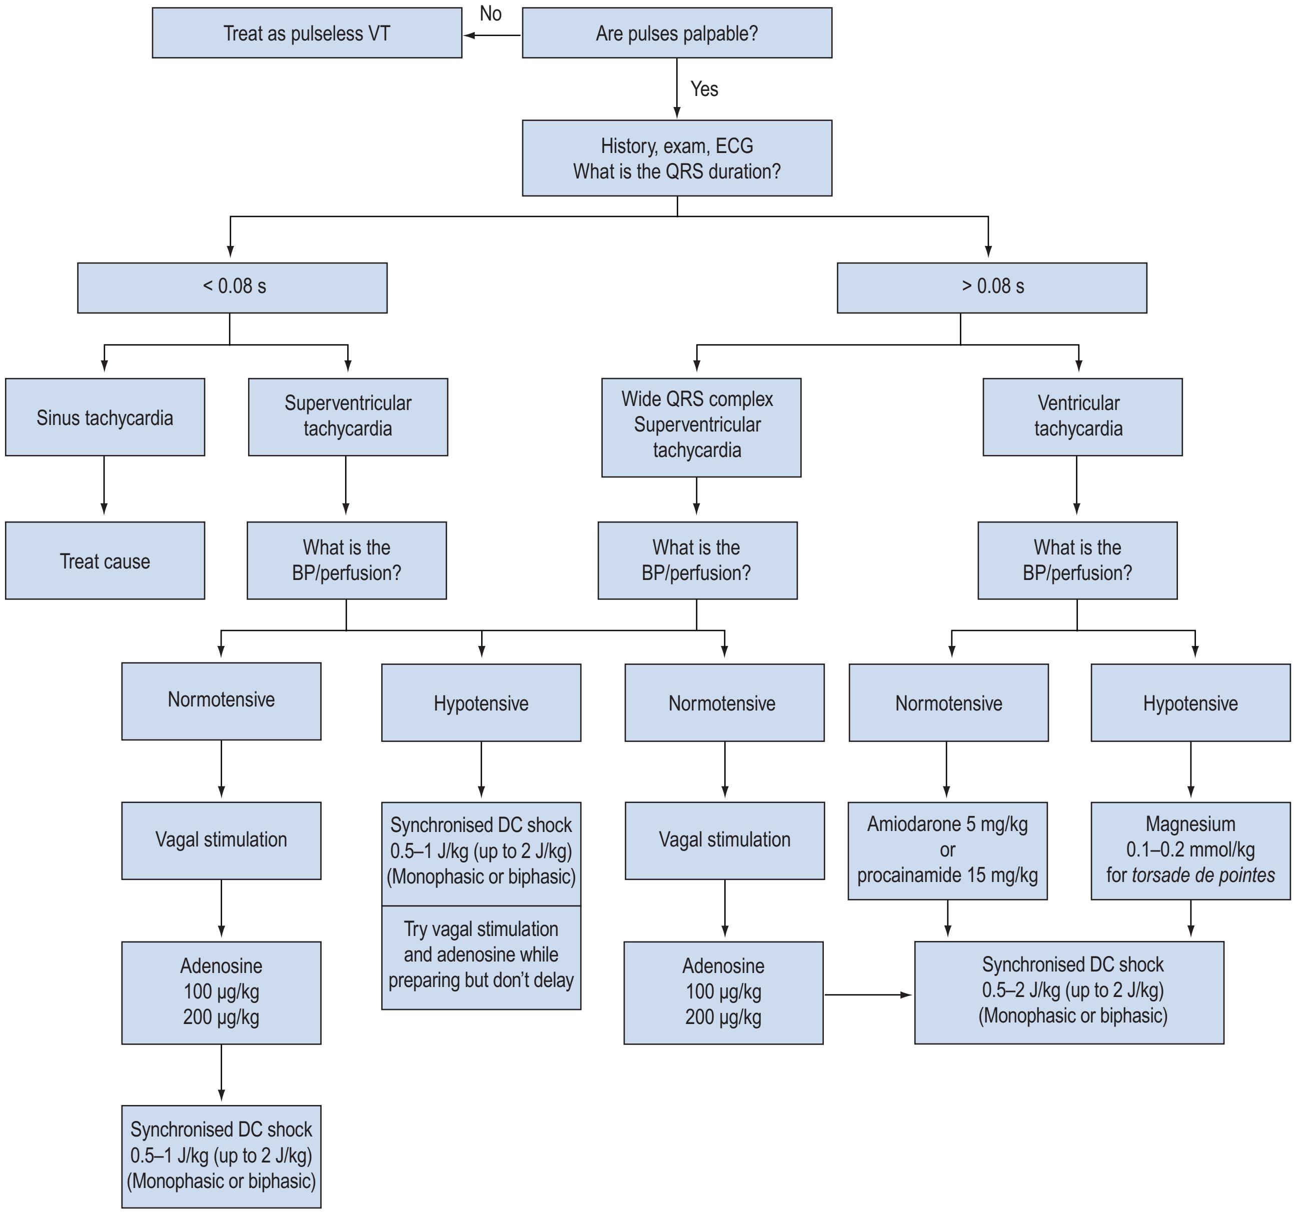

Figure 113.3 Treatment of tachyarrhythmias. *(Reproduced with permission from the Australian Resuscitation Council, Melbourne.)*

- *hyperkalaemia:* may be antagonised with a calcium salt then the serum level lowered with insulin (0.05 U/kg)+dextrose (0.5 g/kg), but beware of hypoglycaemia. Additional treatments of hyperkalaemia are salbutamol, sodium bicarbonate, hyperventilation or combinations.

All drugs should be flushed into the circulation with a small bolus of isotonic fluid. To prevent their inactivation, drugs should not be mixed together in the syringe or in infusion lines.

ASYSTOLE AND BRADYCARDIA

Asystole and hypotensive bradycardia (<60 beats/min) should be treated with epinephrine 10 μg/kg i.v. or i.o. If these routes are not available, epinephrine 100 μg/kg should be administered via endotracheal tube (ETT).

Unresponsive asystole should be treated with additional similar doses of epinephrine (10 μg/kg i.v., i.o.; 100 μg/kg ETT) every 3–5 minutes. Higher doses, up to 200 μg/kg i.v. or i.o., may be indicated in special circumstances (e.g. beta-blocker toxicity) but should not

be used routinely as they have not altered outcome and predispose to complications (post-arrest myocardial dysfunction, hypertension, tachycardia). In newly born infants, the initial bolus dose is 100–300 μg/kg.

Recurrent bradycardia or asystole may require an infusion of epinephrine at 0.05–3 μg/kg per min: doses <0.3 μg/kg per min are predominantly beta adrenergic; doses >0.3 μg/kg per min are predominantly alpha adrenergic. Infuse into a secure large vein. If sinus rhythm cannot be restored, sodium bicarbonate 1 mmol/kg i.v. or i.o. may be helpful, but do not allow mixing with epinephrine since catecholamines are inactivated in alkaline solution.

Sinus bradycardia, sinus arrest with slow junctional or idioventricular rhythm, and atrioventricular block are the most common preterminal arrhythmias in paediatric practice. Untreated, bradycardia progresses to asystole. Bradycardia caused by vagal stimulation should be managed with cessation of the stimulus and/or atropine 20 μg/kg i.v. or i.o. (minimum dose 100 μg) but persistent vagal-mediated bradycardia should be treated with epinephrine 10 μg/kg i.v. or i.o.

If facilities are available, bradycardia may be treated with pacing (oesophageal, transcutaneous, transvenous, epicardial) if sinus node dysfunction or heart block exists, but it is not helpful in asystole.

VENTRICULAR FIBRILLATION AND PULSELESS VENTRICULAR TACHYCARDIA

The initial dose for ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) is a single unsynchronised DC shock of 4 J/kg followed by immediate resumption of ECC without pausing to analyse the rhythm. If VF or pulseless VT persists, subsequent single shocks of 4 J/kg are given, each followed by 2 minutes of ECC. Higher doses may be given in refractory VF.

Failure of VF to revert to sinus rhythm after the first shock should also be treated with epinephrine 10 μg/kg i.v. or i.o. or 100 μg/kg ETT every 3–5 minutes. Persistent (refractory) or recurrent VF or VT may also be treated with the antiarrhythmic drug amiodarone interspersed with single DC shocks. The dose of amiodarone is 5 mg/kg i.v. or i.o. as a bolus, which may be repeated to a maximum of 15 mg/kg. If amiodarone is not available, lidocaine in a dose of 1 mg/kg i.v. or i.o. or 2–3 mg/kg via ETT may be used, but the evidence for its efficacy is poor. An infusion of lidocaine at 20–50 μg/kg per min may be used to suppress excitability. Alternatives to epinephrine as a vasopressor, such as other catecholamines or vasopressin, have not been adequately investigated for use during CPR for children.

The witnessed (monitored) onset of VF or pulseless VT, such as in the cardiac catheter laboratory or intensive care unit setting, should be treated with successive (if needed) unsynchronised DC shocks up to a stack (salvo) of three shocks all of 4 J/kg. Rescuers should maintain the paddles on the chest and be prepared to deliver the series of the three shocks in quick succession, pausing only to verify the rhythm. Automatic external defibrillators are not suitable for this purpose because of time delays in their recognition of rhythms and charging. A precordial thump may be given before DC shock but its efficacy has not been proven.

Magnesium, 25–50 mg/kg (0.1–0.2 mmol/kg) i.v. or i.o., is indicated for polymorphic VT (*torsade de pointes*).

ELECTROMECHANICAL DISSOCIATION AND PULSELESS ELECTRICAL ACTIVITY

A normal ECG complex without pulse or circulation is called electromechanical dissociation (EMD). If untreated, the ECG initially deteriorates to an abnormal but still recognisable state when it is called pulseless electrical activity (PEA). Both conditions should be treated as for asystole and their causes ascertained and treated.

PULSATILE VENTRICULAR TACHYCARDIA

Haemodynamically stable VT may be treated with an antiarrhythmic agent such as amiodarone (5 mg/kg i.v. over 20–60 minutes) or procainamide (15 mg/kg i.v. over 30–60 minutes). Since both drugs prolong the QT interval, they should not be given together. If *torsade de pointes* is present, magnesium (25–50 mg/kg, 0.1–0.2 mmol/kg i.v. or i.o.) may be used. If cardioversion is needed, it should be synchronised at 0.5–2 J/kg under sedation/anaesthesia. Pulsatile VT may be difficult to distinguish from wide-complex supraventricular tachycardia (SVT) when its QRS duration is >0.08 seconds.

SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT) is the most common spontaneous arrhythmia in childhood and infancy. It may cause life-threatening hypotension. It is usually re-entrant with a rate of 220–300/min in infants, less in children. The QRS complex is usually narrow (<0.08 seconds) making it difficult sometimes to discern from sinus tachycardia (ST). However, whereas ST is a part of other features of illness, SVT is a singular entity, and whereas the rate in ST is variable with activity or stimulation, it is uniform in SVT. In both rhythms, a P-wave may be discernible. SVT with aberrant conduction (QRS>0.08 seconds) may resemble VT. Relative treatment of these tachycardias is summarised in Figure 113.3.

If SVT is haemodynamically stable (adequate perfusion and blood pressure), initial treatment should be vagal stimulation. For infants and young children, application to the face of a plastic bag filled with iced water is often effective. Older children may be treated with carotid sinus massage or guided to perform a Valsalva (e.g. blowing through a narrow straw). If the patient is ventilated, apply vagal stimulation by tracheal or pharyngeal suction. If vagal stimulation is

unsuccessful, give adenosine 100 µg/kg i.v. (maximum 6 mg) as a rapid bolus aided by an injection of 0.9% saline. If unsuccessful, double the dose to 200 µg/kg (maximum 12 mg) and again inject rapidly. An adenosine-induced pro-tachyarrhythmia (e.g. *torsade de pointes*) is rare.

An alternative drug treatment of haemodynamically stable SVT is amiodarone whose schedules are either infusions of 5 mg/kg over 1 hour followed by 5 µg/kg/min, or initially 25 µg/kg/min for 4 hours followed by 5–15 µg/kg/min. Amiodarone may cause hypotension, hypothyroidism and pulmonary toxicity. Other alternative drugs include procainamide in a dose of 15 mg/kg i.v. over 30–60 minutes, digoxin, a beta blocker or a calcium channel blocker. However, calcium channel blockers should not be used at all to treat SVT in infants and should be avoided or used with extreme caution in children because they may induce hypotension and cardiac depression. Haemodynamically stable SVT unresponsive to vagal stimulation and drug therapy may be treated with synchronised DC shock (cardioversion) in a dose of 0.5–1.0 J/kg.

SVT may cause severe hypotension or pulselessness, in which case synchronised DC shock (cardioversion) at 0.5–1.0 J/kg should be given immediately, progressing to 2 J/kg if necessary. While preparations are made to give DC shock, vagal stimulation and adenosine (i.v. or i.o.) may be tried provided they do not delay cardioversion.

POST-RESUSCITATION CARE

Supportive therapy should be provided until there is recovery of function of vital organs. This may require provision of oxygen therapy, mechanical ventilation, inotropic/vasopressor infusion, renal support, parenteral nutrition and other therapy for several days or longer. However, the percentage of inspired oxygen should be reduced as soon as possible after resuscitation to achieve only normal levels of Pa_{O_2}. Hyperoxaemia, like hypoxaemia, should be avoided. Recovery of infants and children is usually slow because cardiorespiratory arrest is often secondary to prolonged global ischaemia or hypoxaemia, which implies that other organs sustained damage before cardiorespiratory arrest. Particular care should be taken to ensure adequate cerebral perfusion with well-oxygenated blood. Hyperventilation is not useful for this purpose.

Therapeutic hypothermia post resuscitation (32–34°C) up to 3 days may improve neurological outcome, but is controversial and may predispose to infection and coagulopathy. However, an inadvertently hypothermic patient (e.g. one nearly drowned in icy water), provided the temperature is above 33°C, should not initially be actively warmed. During therapeutic hypothermia, shivering should be prevented with sedation and/or neuromuscular blockade, seizures should be actively sought and treated with anticonvulsant and the cause of the CPA should be investigated and treated appropriately (e.g. sepsis or drug overdose). Hyperthermia should be aggressively treated, in all instances.

Complications of CPR should be sought, especially if secondary deterioration occurs. A chest X-ray should be obtained to check the position of the endotracheal tube, to exclude pneumothorax, lung collapse, contusion or aspiration, and to check the cardiac silhouette – although an echocardiographic examination is preferable to specifically check contractility and to exclude a pericardial effusion. Measurements of haemoglobin, pH, gas tensions, electrolytes and glucose are important.

CESSATION OF CARDIOPULMONARY RESUSCITATION

Long-term outcome from paediatric CPR is mediocre, but better if arrest is respiratory alone or if CPA occurs in hospital. The decision to cease CPR should be based on a number of factors including the duration and quality of resuscitation, response to treatment, pre-arrest status, remediable factors, likely outcome if ultimately successful, opinions of personnel familiar with the patient and, whenever appropriate, the informed wishes of the parents. In general, unless hypothermia or drug toxicity exists, survival to normality is unlikely if there has been a failure to respond to full competent CPR after 30 minutes and several doses of epinephrine. In the newly born infant, discontinuation of treatment is appropriate if CPR does not establish a spontaneous circulation within 10–15 minutes. Family members should be kept informed, allowed to be present or asked if they want to be present during resuscitation.

POST-RESUSCITATION STAFF MANAGEMENT

Unfortunately, CPA occurring in hospital is often unexpected – for example, when a moribund patient arrives unannounced in the emergency department, a patient's condition deteriorates rapidly on the ward or when a mishap occurs under anaesthesia. These situations test the readiness, training, abilities and skills of individuals and the organisation of the institution. Performance should be audited with a view to improvement. These events have significant psychological impact on individuals and sensitive debriefing sessions should be encouraged.

Appendix 1

Normal biochemical values

Refer to local reference range for site specific interpretation

I BLOOD CHEMISTRY

S=serum
P=plasma
HWB=heparin whole blood

α_1-Acid glycoprotein (S)		0.5–1.4 g/L
Aldosterone (S)	Supine:	140–530 pmol/L
	Erect:	220–970 pmol/L
Ammonia (P) to lab without delay		4–50 µmol/L
Amylase (S or P)		70–300 U/L
α_1-Antitrypsin (S or P)		2.1–4.0 g/L
Aspartate aminotransferase (AST) (P)		6–42 U/L
Bicarbonate (P)		22–32 mmol/L
Bilirubin (total) (S or P)		3–17 µmol/L
Bilirubin (direct) (S or P)		2–9 µmol/L
Caeruloplasmin (S or P)		0.20–0.60 g/L
Calcium (S or P)		2.25–2.65 mmol/L
Carotene (S or P)		1.0–4.8 µmol/L
Chloride (S or P)		98–108 mmol/L
Cholesterol (S or P)		3.1–6.5 mmol/L
Copper (S or P)		11–23 µmol/L
Cortisol (S or P)	8–9 a.m.	300–800 nmol/L
	4–5 p.m.	100–600 nmol/L
Creatinine (P)		50–120 µmol/L
Creatinine clearance		>1.3 mL/s
Creatinine kinase (P)		20–130 U/L
Creatinine kinase MB isoenzymes		<7 µg/L
Digoxin (S)	Toxic	>2 µg/L
Effective thyroxine ratio (ETR) (S)		0.90–1.09
FSH (S) Male		3–19 U/L
Female Follicular		5–20 U/L
Mid-cycle		15–30 U/L
Luteal		5–15 U/L
Postmenopausal		50–100 U/L
Glucose (fasting) (fluoride) (P)		3.9–6.2 mmol/L
γ-Glutamyl transferase (γ-GT) (P)	F	7–30 U/L
	M	10–50 U/L
Growth hormone (fasting, resting) (S)	M	<6 mU/L
	F	<16 mU/L
	Child	<10 mU/L
Insulin (fasting) (S)		3–28 mU/L
Iron (S or P) (1) Iron	M	14–31 µmol/L
8–10 a.m.	F	11–29 µmol/L
(2) Iron-binding capacity	M	41–70 µmol/L
	F	37–77 µmol/L

Continued

Lactate (special collection)		0.3–1.3 mmol/L
LDH (S or P)		<80 U
Lead (HWB)		<2 µmol/L
Lithium (S) not plasma		0.8–1.2 mmol/L (therapeutic range)
Magnesium (S or P)		0.7–1.1 mmol/L
Oestriol (pregnancy) (S)		Depends on gestation
Osmolality (S or P)		275–295 mOsm/kg
Phosphatase		
A. Prostatic (S or P) (stabilise plasma with 5 mg/mL of $NaHSO_4$ or freeze)		0–4 U/L
B. Alkaline (S or P)		100–350 U/L
Phosphate (inorganic) (P)		0.8–1.4 mmol/L
Porphyrins (red cell) (HWB)		<1.2 µmol/L
Potassium (P)		3.4–5.0 mmol/L
Prolactin (S) (resting)		25 µg/L
Proteins		
A. (1) Total (S)		63–78 g/L
(2) Albumin (S)		35–45 g/L
B. Electrophoresis (S) not plasma:		
Albumin		35–45 g/L
α_1-Globulin		2–4 g/L
α_2-Globulin		5–9 g/L
β-Globulin		6–10 g/L
γ-Globulin		8–16 g/L
Pyruvate (special collection)		30–80 µmol/L
Renin (special tubes – keep blood cold)		
100–180 mmol Na intake:		
Supine (6 hours)		<0.58 ng/s/L
Upright (4 hours)		0.28–1.25 ng/s/L
Sodium (P)		134–146 mmol/L
Thyroxine (S)		60–150 nmol/L
Transferrin (S or P)		2.1–3.5 g/L
Triglyceride (fasting) (P)		1.80 mmol/L
Tri-iodothyronine (S)		1.3–2.9 nmol/L
Troponin T		<30 ng/L
TSH (S)		1–11 mU/L
Urea (P)		3.0–8.0 mmol/L
Uric acid (P)	M	0.18–0.48 mmol/L
	F	0.12–0.42 mmol/L
Zinc (P)		12–20 µmol/L

II URINE

AA=20 mL 50% acetate
d=24-hour collection
Sp= spot urine

Aldosterone (d, AA)		14–55 nmol/d
ALA (delta amino laevulinic acid) (Sp or d, AA)	Sp:	<50 µmol/L
	d:	10–50 µmol/d
Amylase (Sp or d, *no acid*)	Sp:	<900 U/L
	d:	100–1000 U/d
Calcium (d, AA)		<7.5 mmol/d

Continued

Catecholamines and derivatives (d, 20 mL 50% HCl):		
1. HMMA (VMA) Hydroxymethoxymandelic acid		<35 µmol/d
2. Metepinephrine		<5.6 µmol/d
3. Catecholamine		<1.6 µmol/d
Copper (d, AA)		<1.6 µmol/d
Coproporphyrin (collect 24-hour urine into 8 g sodium carbonate)		<245 nmol/d
Creatinine (d, AA)		10–20 mmol/d
5-Hydroxyindole-acetic acid (5-HIAA) (d, AA)		5–37 µmol/d
Hydroxyproline (d, AA)		<0.35 mmol/d (gelatin-free diet)
Indican (d, AA)		0.04–0.36 mmol/d
Lead (d, AA)		0.4 µmol/d
Magnesium (d, AA)		2.0–6.6 mmol/d
Melanin (fresh Sp)		Qualitative
Oestriol (in pregnancy) (d, AA)		50–160 µmol/d at 36 weeks' gestation
Osmolality (Sp)		300–1300 mOsm/kg
Oxalate (d, AA)		<300 µmol/d
Phosphorus (d, AA)		10–42 mmol/d
Porphobilinogen (fresh Sp)		Qualitative
Potassium (d or Sp, AA)		25–100 mmol/d
Protein (d or Sp, AA)		0.02–0.06 g/d
Sodium (d or Sp, AA)		40–210 mmol/d
Steroids (d, AA):		
1. 17-Oxosteroids	M	28–80 µmol/d
	F	14–60 µmol/d
2. 17-Hydroxy corticosteroids	M	14–70 µmol/d
	F	7–50 µmol/d
Urea (d or Sp, AA)		170–500 mmol/d
Uric acid (d, 8 g sodium carbonate)		<3.6 mmol/d (purine-free diet)
Urobilinogen (fresh Sp)		Qualitative
Uroporphyrin (collect as for coproporphyrin)		<50 nmol/d
Xylose absorption:		
Xylose excretion in 5 hours		>27 mmol
Plasma value at 2 hours		1.7–3.4 mmol/L

III FAECES

Fat (3-day collection)	<5 g/L
Porphyrins (single stool)	
Coproporphyrins	<30 nmol/g dry wt
Protoporphyrins	<135 nmol/g dry wt

IV CSF

Protein	0.15–0.45 g/L
Glucose	2.7–4.2 mmol/L
IgG	<0.05 g/L
IgG : total protein ratio	5–14%

Appendix 2

Système International (SI) units

BASIC SI UNITS			PREFIXES					
Physical quantity	Name	Symbol	Factor	Name	Symbol	Factor	Name	Symbol
Length	Metre	m	10^{18}	Exa-	E	10^{-18}	Atto-	a
Mass	Kilogram	kg	10^{15}	Peta-	P	10^{-15}	Femto-	f
Time	Second*	s	10^{12}	Tera-	T	10^{-12}	Pico-	p
Electric current	Ampere	A	10^{9}	Giga-	G	10^{-9}	Nano-	n
Thermodynamic temperature	Kelvin	K	10^{6}	Mega-	M	10^{-6}	Micro-	μ
Luminous intensity	Candela	cd	10^{3}	Kilo-	k	10^{-3}	Milli-	m
Amount of substance	Mole	mol	10^{2}	Hecto-	h	10^{-2}	Centi-	c
			10^{1}	Deca-	da	10^{-1}	Deci-	d

*Minute (min), hour (h) and day (d) will remain in use although they are not official SI units.

DERIVED SI UNITS

Quantity	SI units	Symbol	Expression in terms of SI base units or derived units
Frequency	Hertz	Hz	1 Hz = 1 cycle/s (1 s^{-1})
Force	Newton	N	1 N = 1 kg.m/s^2 (1 kg.m.s^{-2})
Work, energy, quantity of heat	Joule	J	1 J = 1 N.m (1 kg.m^2.s^{-2})
Power	Watt	W	1 W = 1 J/s (1 J.s^{-1})
Quantity of electricity	Coulomb	C	1 C = 1 A.s
Electric potential, potential difference, tension, electromotive force	Volt	V	1 V = W/A (1 W.A^{-1})
Electric capacitance	Farad	F	1 F = 1 A.s/V (A.s.V^{-1})
Electric resistance	Ohm	W	1 W = 1 V/A (1 V.A^{-1})
Flux of magnetic induction, magnetic flux	Weber	Wb	1 Wb = 1 V.s
Magnetic flux density, magnetic induction	Tesla	T	1 T = 1 Wb/m^2 (1 Wb.m^{-2})
Inductance	Henry	H	1 H = 1 V.s/A (V.s.A^{-1})
Pressure	Pascal	Pa	1 Pa = 1 N/m^2 (1 N.m^{-2})
			= 1 kg/m^2.s^2 (1 kg.m^{-2}.s^2)

The litre (L) (10^{-3} m^3 = dm^3), though not official, will remain in use as a unit of volume, as also will the dyne (dyn) as a unit for force (1 dyn = 10^{-5} N).

PRESSURE MEASUREMENTS

SI unit	Old unit	Conversion factors: Old to SI (exact)	Conversion factors: SI to old (approx.)
kPa	mmHg	0.133	7.5
kPa	1 standard atmosphere (approx. 1 Bar)	101.3	0.01
kPa	cmH_2O	0.0981	10
kPa	lb/sq in	6.894	0.145

HAEMATOLOGY

Measurement	SI unit	Old unit	Conversion factors: Old to SI	Conversion factors: SI to old
Haemoglobin (Hb)	g/dL	g/100 mL	Numerically	equivalent
Packed cell volume	No unit*	Per cent	0.01	100
Mean cell Hb concentration	g/dL	Per cent	Numerically	equivalent
Mean cell Hb	pg	µug	Numerically	equivalent
Red cell count	Cells/litre	Cells/mm^3	10^6	10^{-6}
White cell count	Cells/litre	Cells/mm^3	10^6	10^{-6}
Reticulocytes	Per cent	Per cent	Numerically	equivalent
Platelets	Cells/litre	Cells/mm^3	10^6	10^{-6}

*Expressed as decimal fraction.

PH pH	$[H^+]$ nmol/litre
6.80	158
6.90	126
7.00	100
7.10	79
7.20	63
7.25	56
7.30	50
7.35	45

7.60	25
7.70	20

Appendix 3

Respiratory physiology symbols and normal values

SYMBOLS

Primary		Secondary symbols for gas phase	
C	Concentration of gas in blood	A	Alveolar
F	Fractional concentration in dry gas	B	Barometric
f	Frequency of respiration (breaths/min)	D	Dead space
P	Pressure or partial pressure	E	Expired
Q	Volume of blood	I	Inspired
$\dot{Q}$	Volume of blood per unit time	L	Lung
R	Respiratory exchange ratio	T	Tidal
S	Saturation of haemoglobin with O_2	*Secondary symbols for blood phase*	
$\dot{V}$	Volume of gas per unit time	a	arterial
		c	capillary
		ć	end-capillary
		i	ideal
		v	venous
		$\bar{v}$	mixed venous

– above any symbol denotes a mean value.
· above any symbol denotes a value per unit time.

NORMAL VALUES

1. **Blood**
   (a) *Arterial*

pH	:	7.36–7.44	(H^+=44–36 nmol/L)
PaO	:	85–100 mmHg	(11.3–13.3 kPa)
$PaCO_2$	:	36–44 mmHg	(4.8–5.9 kPa)
O_2 content	:	20–21 vols%	(8.9–9.4 nmol/L)
CO_2 content	:	48–50 vols%	(21.6–22.5 nmol/L)

   (b) *Venous*

pH	:	7.34–7.42	(H^+=38–46 nmol/L)
PO_2	:	37–42 mmHg	(5–5.6 kPa)
PCO_2	:	42–50 mmHg	(5.6–6.7 kPa)
O_2 content	:	15–16 vols%	(6.7–7.2 mmol/L)
CO_2 content	:	52–54 vols%	(23.3–24.2 mmol/L)

2. **Gases**
   (a) *Inspired air*

O_2	:	20.93%	
PI_{O_2}	:	149 mmHg	(19.9 kPa)
N_2	:	79.04%	
PI_{N_2}	:	563 mmHg	(75 kPa)
CO_2	:	0.03%	

   (b) *Expired air*

O_2	:	16–17%	
PE_{O_2}	:	113–121 mmHg	(15–16 kPa)
N_2	:	80%	
PE_{N_2}	:	579 mmHg	(77 kPa)
CO_2	:	3–4%	
PE_{CO_2}	:	21–28 mmHg	(2.8–3.7 kPa)

3. **Ventilation : perfusion**
   (a) *Alveolar–arterial oxygen gradient:*
   5–20 mmHg (0.7–2.7 kPa) breathing air
   25–65 mmHg (3.3–8.6 kPa) breathing 100% oxygen
   (b) *Venous admixture* ($\dot{Q}_S : \dot{Q}_T$): 5% of cardiac output
   (c) *Right to left physiological shunt*: 3% of cardiac output
   (d) *Anatomical dead space*: 2 mL/kg body weight
   (e) *Dead space : tidal volume ratio* $V_D : V_T$): 0.25–0.4 or 33+(Age/3) percent
4. **Lung volumes**
   Approximate values in adults are listed. Values are less in smaller subjects and in females.

Tidal volume	:	400 mL or 6 mL/kg
Inspiratory capacity	:	3.6 litres
Inspiratory reserve volume	:	3.1 litres
Expiratory reserve volume	:	1.2 litres
Functional residual capacity	:	2.4 litres
Residual volume	:	1.2 litres
Total lung capacity	:	6.0 litres
Vital capacity	:	4.8 litres

   or 2.5 L/sq m body surface *or* 2.5 L/m height in males
   2.0 L/sq m body surface *or* 2.0 L/m height in females
   or 65–75 mL/kg
5. **Lung mechanics**

(a) *Peak expiratory flow rate*	:	450–700 L/min (males)	
	:	300–500 L/min (females)	
(b) *Forced expiratory volume in 1 second* (FEV_1)	:	70–83% of vital capacity	
(c) *Compliance* (approximate values)			
(i) Lung compliance (CL)			
		Static	*Dynamic*
conscious (erect)	:	200 mL/cmH_2O	180 mL/cmH_2O
paralysed anaesthetised (supine)*	:	160 mL/cmH_2O	80 mL/cmH_2O
(ii) Chest wall compliance (CCW)	:	200 mL/cmH_2O	
(iii) Total compliance (CT):			
conscious (erect)	:	150 mL/cmH_2O	100 mL/cmH_2O
paralysed anaesthetised (supine)*	:	74 mL/cmH_2O	56 mL/cmH_2O
(d) *Airways resistance*:			
conscious	:	0.6–3.2 cmH_2O/L per second	
sedated, partially paralysed and ventilated (includes resistance of endotracheal tube and catheter mount)	:	5–10 H_2O/L per second	

   (e) *Work of breathing*: 0.3–0.5 kg m/min
   or oxygen consumption of 0.5–1 mL/L ventilation

*Compliance values would be lower for the sedated, partially paralysed, ventilated patient in the intensive care unit, i.e. effective dynamic compliance=40–50 mL/cmH_2O.

6. **Cardiovascular** – pressures in kPa are given within brackets

(a)	Cardiac index	:	2.5–3.6 L/min per m^2
(b)	Stroke volume	:	42–52 mL/m^2
(c)	Ejection fraction	:	0.55–0.75
(d)	End-diastolic volume	:	75±15 mL/m^2
(e)	End-systolic volume	:	25±8 mL/m^2
(f)	Left ventricular stroke work index	:	30–110 g-m/m^2
(g)	Left ventricular minute work index	:	1.8–6.6 kg-m/min per m^2
(h)	Oxygen consumption index	:	110–150 mL/L
(i)	Right atrial pressure	:	1–7 mmHg (0.13–0.93)
(j)	Right ventricular systolic pressure	:	15–25 mmHg (2.0–3.3)
(k)	Right ventricular diastolic pressure	:	0–8 (0–1)
(l)	Pulmonary artery systolic pressure	:	15–25 mmHg (2.0–3.3)
(m)	Pulmonary artery diastolic pressure	:	8–15 mmHg (1–2)
(n)	Pulmonary artery mean pressure	:	10–20 mmHg (1.3–2.7)
(o)	Pulmonary capillary wedge pressure	:	6–15 mmHg (0.8–2.0)
(p)	Systemic vascular resistance	:	770–1500 dyne-s/cm^5
		:	77–150 kPa-s/L
(q)	Pulmonary vascular resistance	:	20–120 dyne-s/cm^5
		:	2–12 kPa-s/L

Appendix 4

Physiological equations

RESPIRATORY EQUATIONS

(a) *Oxygen consumption* (250 mL/min)
Oxygen consumption = amount of oxygen in inspired gas minus amount in expired gas

i.e. $$\dot{V}O_2 = (\dot{V}I \times FI_{O_2}) - (\dot{V}E \times FE_{O_2})$$

(b) *Carbon dioxide production* (200 mL/min)
Volume CO_2 eliminated in expired gas = expired gas volume × CO_2 concentration in mixed expired gas

i.e. $$\dot{V}CO_2 = \dot{V} \times F\bar{E}_{CO_2}$$

As expired volume is made up of alveolar and dead space gas,

$$\dot{V}CO_2 = (\dot{V}A \times FA_{CO_2})(\dot{V}D \times FI_{CO_2})$$

As Fi_{CO_2} is negligible, especially if there is no rebreathing,

$$\dot{V}CO_2 = \dot{V}A \times FA_{CO_2}$$

or $$FA_{CO_2} = \frac{\dot{V}CO_2}{\dot{V}A}$$

or $$PA_{CO_2}(\text{mmHg}) = \frac{\dot{V}_{CO_2}(\text{mL/min STPD})}{\dot{V}A(\text{L/min BTPS})} \times 0.863$$

or $$PA_{CO_2}(\text{kPa}) = \frac{\dot{V}_{CO_2}(\text{mmol/min})}{\dot{V}A(\text{L/min BTPS})} \times 2.561$$

STPD: Standard temperature (0°C) and pressure (760 mmHg or 101.35 kPa) dry gas
BTPS: Body temperature and ambient pressure, saturated with water vapour

(c) *Physiological dead space*

Bohr's equation, $$\frac{V_D}{V_T} = \frac{PA_{CO_2} - P\bar{E}_{CO_2}}{PA_{CO_2}}$$

or $$\frac{V_D}{V_T} = \frac{Pa_{CO_2} - P\bar{E}_{CO_2}}{Pa_{CO_2}}$$

(d) *Alveolar oxygenation*

$$PA_{O_2} = PI_O - \frac{Pa_{CO_2}}{R}$$

where R is the respiratory quotient (normally 0.8).

$$PA_{O_2} = PI_{O_2} - Pa_{CO_2}\left(\frac{PI_{O_2} - P\bar{E}_{O_2}}{P\bar{E}_{CO_2}}\right)$$

or $$PA_{O_2} = PI_{O_2} - PA_{CO_2}\left(\frac{FI_{O_2} + 1 - FI_{O_2}}{R}\right)$$

when FI_{O_2} = 1.0 (patient breathing 100% oxygen),

then $PA_{O_2} = (PB - \text{saturated water vapour pressure}) - PA_{CO_2}$
$= (PB - 47) - Pa_{CO_2}$

(e) *Venous admixture*

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{Cc'_{O_2} - Ca_{O_2}}{Cc'_{O_2} - C\bar{v}_{O_2}}$$
$$= \frac{(PA_{O_2} - Pa_{O_2}) \times 0.0031}{CaO_2 + (PA_{O_2} - Pa_{O_2}) \times 0.0031 - C\bar{v}_{O_2}}$$
$$= \frac{(PA_{O_2} - Pa_{O_2}) \times 0.0031}{(PA_{O_2} - Pa_{O_2}) \times 0.0031 + 5} \text{ (simplified)}$$

(f) *Fractional inspired oxygen concentration*

$$Fi_{O_2} = \frac{O_2 \text{ flow in L/min} + (\text{air flow in L/min} \times 0.21)}{\text{Total } O_2 + \text{air flow in L/min}}$$

(g) *Henderson–Hasselbalch equation*

$$\text{pH} = \text{pKA} + \log\frac{(HCO_3^-)}{(CO_2)}$$

$$\text{pH} = 6.1 + \log\frac{(HCO_3^- \text{ in mmol/L})}{(PCO_2 \text{ in mmHg}) \times 0.03}$$

$$[H^+]\text{ nmol/L} = 24 \times \frac{(PCO_2 \text{ in mmHg})}{(HCO_3^- \text{ in mmol/L})}$$

$$[H^+]\text{ nmol/L} = 180 \times \frac{(PCO_2 \text{ in kPa})}{(HCO_3^- \text{ in mmol/L})}$$

CARDIOVASCULAR EQUATIONS

(a) *Mean blood pressure* (BP) = DBP + ⅓ (SBP – DBP)
(b) *Rate pressure product* (RPP) = P × SBP
(c) *Body surface area* (BSA) in $m^2 = (Ht)^{0.725} \times (Wt)^{0.425} \times 71.84 \times 10^{-4}$
(d) **Cardiac index* (CI) $= \frac{CO}{BSA}$ = mL/min per m^2
(e) *Stroke volume* (SV) $= \frac{CO}{P}$ = mL/beat
(f) **Stroke volume index* (SVI) $= \frac{SV}{BSA}$ = mL/beat per m^2
(g) **Left ventricular stroke work index* (LVSWI) = (BP – PCWP) (SVI) (0.0136) = g-m/m^2 per beat
(h) *Systemic vascular resistance* (SVR) $= \frac{BP - RAP}{CO}$ resistance units

(Multiply × 79.9 to convert to absolute resistance units, dynes-s cm^{-5})

(i) *Pulmonary vascular resistance* (PVR) $= \frac{PAP - PCWP}{CO}$ resistance units

(Multiply × 79.9 to convert to absolute resistance units, dynes-s cm^{-5})

(j) *Left ventricular pre-ejection period* (PEP) = QS_2 – LVET m s
(k) *Other systolic time index ratios* may easily be calculated:

$$\frac{1}{PEP^2} \text{ and } \frac{PEP}{LVET}$$

*For interpatient comparisons and reference standards, the 'index' term, output normalised to body surface, may be used when:

SBP = systolic blood pressure in mmHg
DBP = diastolic blood pressure in mmHg
P = heart rate in beats/min
Ht = height in cm
Wt = weight in kg
CO = cardiac output in mL/min
PCWP = pulmonary capillary wedge pressure in mmHg
RAP = right atrial pressure in mmHg
PAP = mean pulmonary artery pressure in mmHg
LVET = left ventricular ejection time in m s
QS_2 = total electromechanical systole in m s.

RENAL EQUATIONS

(a) *Standard creatinine clearance* (mL/min/1.73 m^2)

$$= \frac{\text{urine creatinine (mmol/L)}}{\text{serum creatinine (mmol/L)}} \times \text{urine volume (mL/min)} \times \frac{1.73}{\text{body surface area (m}^2\text{)}}$$

(b) *Per cent filtered Na^+ excreted*

$$= \frac{\text{urine Na}^+\text{ (mmol/L)}}{\text{serum Na}^+\text{ (mmol/L)}} \times \frac{\text{serum creatinine (mmol/L)}}{\text{urine creatinine (mmol/L)}} \times 100$$

(c) *Free water clearance* (mL/min)

$$= \text{urine volume (mL/min)} - \frac{\text{urine osmolality (mOsm/kg)}}{\text{plasma osmolality (mOsm/kg)}} \times \text{urine volume (mL/min)}$$

(d) *Additional calculated parameters*:

(i) $\frac{\text{urine}}{\text{plasma}}$ osmolality ratio

(ii) $\frac{\text{urine}}{\text{serum}}$ creatinine ratio

(iii) $\frac{\text{blood urine}}{\text{serum creatinine}}$ ratio

(iv) $\frac{\text{urine}}{\text{plasma}}$ urea ratio

(v) urinary Na^+ and K^+ excretion (mmol)

(vi) $\frac{\text{urinary Na}^+}{\text{urinary K}^+}$ ratio

Appendix 5

Plasma drug concentrations and American nomenclature

AMERICAN NOMENCLATURE

INN (BAN)	USAN
Epinephrine (adrenaline)	Epinephrine
Cinchocaine	Dibucaine
Deferoxamine (sesferrioxamine)	Deferoxamine
Dextropropoxyphene	Propoxyphene
Dihydromorphinone	Hydromorphone
Ergometrine	Ergonovine
Hyoscine	Scopolamine
Isoproterenol (isoprenaline)	Isoproterenol
Meclozine	Meclizine
Mepivacaine	Carbocaine
Methylamphetamine	Methamphetamine
Norepinephrine (noradrenaline)	Norepinephrine, levarterenol
Orciprenaline	Metaproterenol
Oxybuprocaine	Benoxinate
Paracetamol	Acetaminophen
Pethidine	Meperidine
Salbutamol	Albuterol

Appendix 6
Confirmation of intubation

This is a frequently performed procedure in anaesthesia, in the ICU and in a wide range of emergency situations with very variable availability of sophisticated equipment. It is also the cause of significant morbidity and mortality.

This is a simple checklist that can be modified depending on the equipment available.

Always:

- *Visualise:* the passage of the tip of the endotracheal tube through the vocal cords at intubation, where possible (most reliable but not perfect)
- *Observe:* continuous observation of rise and fall of the chest on ventilation
- *Auscultate:* confirm air entry by auscultation in the axillae and also listen over the stomach. The axillae will confirm bilateral air entry (and indicate endobronchial intubation if air entry is unilateral). Auscultation over the stomach will allow differential breath sounds between axillae and stomach and may indicate oesophageal tube placement if the stomach sounds are louder
- *Observe the patient's colour:* it should remain pink.

Equipment should be available that will also assist includes:

- *Capnography:* CO_2 in the exhaled air is a reliable indicator of correct tube placement. Capnography should always be available for anaesthesia and certainly for transfer of critically ill patients. Ideally, it should be easily available in any ICU
- *Oximetry:* helps to confirm oxygenation.

Of these, visualisation and capnography are most reliable for intubation, but all have a part to play and anyone intubating a patient must have a checklist to confirm correct placement.

'If in doubt, take it out.' Sometimes some of the four basic signs are unconvincing, but if there is any doubt the tube should be replaced or mouth-to-mouth/mask ventilation should be used.

Appendix 7

Parameters monitored and measured by the PiCCO monitor

New non-invasive monitors have introduced some new 'measurements' into clinical practice.

Parameter normal value	Symbol
Pulse contour cardiac output/index CI 3.0–5.0 L/min per m^2 Pulse contour cardiac output is calibrated by means of a simple transcardiopulmonary thermodilution measurement	PCCO/PCCI
Global end-diastolic volume/index 680–800 mL/m^2 (indexed) The total end-diastolic volume of all four chambers of the heart	GEDV/I
Intrathoracic blood volume/index 850–1000 mL/m^2 (indexed) The global end-diastolic volume plus the pulmonary blood volume	ITBV/I
Extravascular lung water/index 3.0–7.0 mL/kg (indexed) Quantifies lung status in terms of pulmonary permeability	EVLW/I
Cardiac function index 4.5–6.5 L/min (indexed) CO/GEDV=preload independent variable of heart function	CFI
Stroke volume/index 40–60 mL/m^2	SV/I
Stroke volume variation <10% Percentage difference of biggest to smallest stroke volumes over the last 30 seconds	SVV
Left ventricular contractility 1200–2000 mmHg/s (159.6–266 kPa/s) Maximum velocity of blood pressure curve corresponds to maximum power or contractility of the left heart	dP/dt_{max}
Systemic vascular resistance/index 1200–2000 dyn/s/cm^{-5} per m^2 (indexed)	SVR/SVRI

EVLW: There are two mechanisms by which the EVLW may be raised: increased intravascular filtration pressure (left heart failure, volume overload), and increased pulmonary vascular permeability as in endotoxic shock and sepsis. There is a direct relationship between the mortality of intensive care patients with acute respiratory distress syndrome and high extravascular lung water.

SVV: Large variations in stroke volume are an indication of reduced intravascular volume (also atrial fibrillation, heart valve disease).

Appendix 8

Mortality/dysfunction risk scores and models

PAEDIATRIC RISK OF MORTALITY (PRISM) SCORE

Mortality risk assessment.

Parameter	Age limit	Ranges		Points
Systolic blood pressure		(mmHg)	(kPa)	
	Infants	130–160	17.3–21.3	2
		55–65	7.3–8.7	2
		>160	>21.3	6
		40–54	5.3–7.2	6
		<40	<5.3	7
	Children	150–200	20–26.7	2
		65–75	8.7–10	2
		>200	>26.7	6
		50–64	6.7–8.5	6
		<50	<6.7	7
Diastolic blood pressure		(mmHg)	(kPa)	
	All ages	>110	>14.6	6
Heart rate (beats/min)	Infants	>160		4
		<90		4
	Children	>150		4
		<80		4
Respiratory rate (breaths/min)	Infants	61–90		1
		>90		5
		Apnoea		5
	Children	51–70		1
		>70		5
		Apnoea		5
$Pa_{O_2} : Fi_{O_2}$ ratio		(mmHg)	(kPa)	
	All ages	200–300	26.6–39.9	2
		<200	<26.6	3
Pa_{CO_2}		(torr (mmHg))	(kPa)	
	All ages	51–65	6.8–8.7	1
		>65	>8.7	5
Pupillary reactions	All ages	Unequal or dilated		4
		Fixed and dilated		10
PT/PTT	All ages	1.5 times control		2
Total bilirubin (mg/dL)	>1 month	>3.5		6
Potassium (mEq/L)	All ages	3.0–3.5		1
		6.5–7.5		1
		<3.0		5
		>7.5		5
Calcium (mg/dL)	All ages	7.0–8.0		2
		12.0–15.0		2
		<7.0		6
		>15.0		6
Glucose (mg/dL)	All ages	40–60		4
		250–400		4
		<40		8
		>400		8
Bicarbonate (mEq/L)	All ages	<16		3
		>32		3

Infants: 0–1 year of age. PRISM score = (systolic blood pressure points) + (diastolic blood pressure points) + (heart rate points) + (respiratory rate points) + (oxygenation points) + (Glasgow Coma Score points) + (pupillary reaction points) + (coagulation points) + (bilirubin points) + (potassium points) + (calcium points) + (glucose points) + (bicarbonate points).

SEPSIS-RELATED ORGAN FAILURE ASSESSMENT (SOFA) SCORE

Easy to calculate, describes the sequence of complications in a critically ill patient rather than predicting outcome.

Organ system	Measure
Respiration	$Pa_{O_2}:Fi_{O_2}$ ratio
Coagulation	Platelet count
Liver	Serum bilirubin
Cardiovascular	Hypotension
Central nervous system	Glasgow Coma Score
Renal	Serum creatinine or urine output

Measure	Finding		Points
$Pa_{O_2}:Fi_{O_2}$ ratio	(mmHg)	(kPa)	
	≥400	≥53.2	0
	300–399	39.9– 53.1	1
	200–299	26.6–39.8	2
	100–199	13.3–26.5	3
	<100	<13.3	4
Platelet count	≥1500/µL		0
	1000–149 999/µL		1
	500–99 999/µL		2
	200–49 999/µL		3
	<200 per µL		4
Serum bilirubin	<1.2 mg/dL		0
	1.2–1.9 mg/dL		1
	2.0–5.9 mg/dL		2
	6.0–11.9 mg/dL		3
	≥12.0 mg/dL		4
Hypotension	(mmHg)	(kPa)	
	Mean arterial pressure ≥70	≥9.3	0
	Mean arterial pressure <70 then (no pressor agents used)	<9.3	1
	Dobutamine any dose		2
	Dopamine ≤5 µg/kg per min		2
	Dopamine >5–15 µg/kg per min		3
	Dopamine >15 µg/kg per min		4
	Epinephrine ≤0.1 µg/kg per min		3
	Epinephrine >0.1 µg/kg per min		4
	Norepinephrine ≤0.1 µg/kg per min		3
	Norepinephrine >0.1 µg/kg per min		4
Glasgow Coma Score	15		0
	13–14		1
	10–12		2
	6–9		3
	3–5		4
Serum creatinine or urine output	Serum creatinine <1.2 mg/dL		0
	Serum creatinine 1.2–1.9 mg/dL		1
	Serum creatinine 2.0–3.4 mg/dL		2
	Serum creatinine 3.5–4.9 mg/dL		3
	Urine output 200–499 mL/day		3
	Serum creatinine >5.0 mg/dL		4
	Urine output <200 mL/day		4

Pa_{O_2} is in mmHg/kPa and Fi_{O_2} in percentages, from 0.21 to 1.00. Adrenergic agents as administered for at least 1 hour with doses in µg/kg per min. A score of 0 indicates normal and a score of 4 indicates most abnormal. Data can be collected and the score calculated daily during the course of the admission. Interpretation: minimum total score: 0; maximum total score: 24. The higher the organ score, the greater is the organ dysfunction. The higher the total score, the greater is the multiorgan dysfunction.

MORTALITY RATE BY SOFA SCORE[1]

Organ system	0	1	2	3	4
Respiratory	20%	27%	32%	46%	64%
Cardiovascular	22%	32%	55%	55%	55%
Coagulation	35%	35%	35%	64%	64%
CNS	32%	34%	50%	53%	56%
Renal	25%	40%	46%	56%	64%

LOGISTIC ORGAN DYSFUNCTION SYSTEM (LODS)

Assess patients for severity of critical organ dysfunction. To predict the probability of death for the patient.

Data collection	During the first 24 hours in the ICU
Data point	If not measured then it is assumed to be normal for scoring purposes
	If several measurements, use the most severe value

LOD score = (neurological score) + (cardiovascular score) + (renal score) + (pulmonary score) + (haematological score) + (hepatic score).

NEUROLOGICAL SCORE

Glasgow coma score	Points
14–15	0
9–13	1
6–8	3
<6	5

Use lowest value. If sedated, estimate the score prior to sedation.

CARDIOVASCULAR SCORE

		Systolic BP		
Heart rate (beats/min)		(mmHg)	(kPa)	Points
30–139	*and*	90–239	11.9–31.8	0
≥140	*or*	240–269	31.9–35.8	1
		70–89	9.3–11.8	1
		≥270	≥35.9	3
		40–69	5.3–9.2	3
<30	*or*	<40	<5.3	5

The most abnormal value for heart rate or systolic blood pressure, either minimum or maximum.

RENAL SCORE

Serum urea nitrogen (mg/dL)		Creatinine (mg/dL)		Urine output (L/d)	Points
<17	*and*	< 1.20	*and*	0.75–9.99	0
17–27.99	*or*	1.2–1.59			1
28–55.99	*or*	≥1.60	*or*	≥10	3
				0.5–0.74	3
≥56					5
				<0.5	5

Highest value for urea nitrogen and for creatinine; if the urine output data are for less than a 24-hour period, adjust that value to 24 hours, assuming the same rate of excretion. On haemodialysis, use the value of urine output prior to initiating haemodialysis

PULMONARY SCORE

On Ventilation or CPAP?		Ratio (Pa_{O_2} (mmHg) : Fi_{O_2})	Ratio (Pa_{O_2} (kPa) : Fi_{O_2})	Points
No				0
Yes	*and*	≥150	≥20	1
Yes	*and*	<150	<20	3

Respiratory support; use the lowest ratio of Pa_{O_2} to Fi_{O_2}.

HAEMATOLOGICAL SCORE

White blood cell count (10^9/L)		Platelet count (10^9/L)	Points
2.5–4.9/µL	*and*	≥50/µl	0
		≥50/µL	1
1–2.4/µL	*or*	<50/µL	1
<1/µL			3

Note: Most abnormal values for the white cell count are either minimum or maximum; minimum platelet count if several values are available.

HEPATIC SCORE[2]

Bilirubin		Prothrombin time	Points
<2.0 mg/dL (< 34.2 µmol/L)	*and*	≤3 seconds above standard (≥25% of standard)	0
≥2.0 mg/dL (≥34.2 µmol/L)	*or*	>3 seconds above standard (<25% of standard)	1

Highest value for bilirubin available. Highest value for prothrombin time in seconds.

MPM II, MORTALITY PROBABILITY MODELS

Excluded
- Age <18 years
- Burn patients
- Coronary care patients
- Cardiac surgery patients
- (The scoring is either present or not present)

Definitions
- Coma or deep stupor at time of ICU admission
  - Not due to drug overdosage
  - If patient is on paralysing muscle relaxant, awakening from anaesthesia or heavily sedated, use best judgement of the level of consciousness prior to sedation
  - *Coma*: no response to any stimulation; no twitching, no movements in extremities, no response to pain or command; Glasgow Coma Score 3
  - *Deep stupor*: decorticate or decerebrate posturing; posturing is spontaneous or in response to stimulation or deep pain; posturing is not in response to commands; Glasgow Coma Score 4 or 5

Heart rate at ICU admission
- Heart rate ≥150 beats/min within 1 hour before or after ICU admission

Systolic blood pressure at ICU admission
- Systolic blood pressure ≤90 mmHg (11.9 kPa) within 1 hour before or after ICU admission

Chronic renal compromise or insufficiency
- Elevation of serum creatinine >2 mg/dL and documented as chronic in the medical record
- If there is the acute diagnosis on chronic renal failure then record only yes for acute renal failure

Cirrhosis
- History of heavy alcohol use with portal hypertension and varices
- Other causes of liver disease with evidence of portal hypertension and varices
- Biopsy confirmation of cirrhosis

Metastatic malignant neoplasm
- Stage IV carcinomas with distant metastases
- Do not include involvement only of regional lymph nodes
- Include if metastases are obvious by clinical assessment or confirmed by a pathology report
- Do not include if metastases not obvious, or if pathology report is not available at the time of ICU admission
- Acute haematological malignancies are included
- Chronic leukaemias are not included unless there are findings attributable to the disease or the patient is under active treatment for the leukaemia. Findings include sepsis, anaemia, stroke caused by clumping of white blood cells, tumour lysis syndrome with elevated uric acid following chemotherapy, pulmonary oedema or the lymphangiectatic form of acute respiratory distress syndrome

Acute renal failure
- Acute tubular necrosis or acute diagnosis on chronic renal failure
- Prerenal azotaemia is not included

Cardiac dysrhythmia
- Cardiac arrhythmia, paroxysmal tachycardia, fibrillation with rapid ventricular response, second- or third-degree heart block
- Do not include chronic and stable arrhythmias

Cerebrovascular incident
- Cerebral embolism, occlusion, cerebrovascular accident, stroke, brainstem infarction, cerebrovascular arteriovenous malformation (acute stroke or cerebrovascular haemorrhage, not chronic arteriovenous malformation)

Gastrointestinal bleeding
- Haematemesis, melaena
- A perforated ulcer does not necessarily indicate GI bleeding; may be identified by obvious ‘coffee grounds’ in nasogastric tube
- A drop of haemoglobin by itself is not sufficient evidence of acute GI bleeding

Intracranial mass effect
- Intracranial mass (abscess, tumour, haemorrhage, subdural) as identified by CT scan associated with any of the following: (1) midline shift; (2) obliteration or distortion of cerebral ventricles; (3) gross haemorrhage in cerebral ventricles or subarachnoid space; (4) visible mass >4 cm; or (5) any mass that enhances with contrast media
- If the mass effect is known within 1 hour of ICU admission, it can be indicated as yes
- CT scanning is not mandated and is indicated only for patients with major neurological insult

Age in years
- Patient’s age at last birthday

CPR within 24 hours prior to ICU admission
- CPR includes chest compression, defibrillation or cardiac massage
- Not affected by the location where the CPR was administered

Mechanical ventilation
- Patient is using a ventilator at the time of ICU admission or immediately thereafter

Medical or unscheduled surgery admission
- Do not include elective surgical patients (surgery scheduled at least 24 hours in advance) or preoperative Swan–Ganz catheter insertion in elective surgery patients

Appendix 9
Therapeutic hypothermia

INDICATIONS

Following cardiac arrest in patients with a return of spontaneous circulation (although the indications may evolve with time).

AIM

A core temperature of 32–34°C as soon as possible and to be maintained at that temperature for 12–24 hours (may evolve).

METHOD

Surface cooling, internal/invasive techniques or a combination of methods can be used. Use sedation and muscle relaxants to prevent discomfort and shivering.

MONITORING

Bladder temperature can be used, as can other methods.

Appendix 10

The Child-Pugh classification

The Child-Pugh classification is a means of assessing the severity of liver cirrhosis.

Score	1	2	3
Bilirubin (μmol/L)	<34	34–50	>50
Albumin (g/L)	>35	28–35	<28
PT (s prolonged)	<4	4–6	>6
Encephalopathy	None	Mild	Marked
Ascites	None	Mild	Marked

If there is primary biliary cirrhosis or sclerosing cholangitis then bilirubin is classified as <68=1; 68–170=2; >170=3.
The individual scores are summed and then grouped as:

- <7=A
- 7–9=B
- >9=C
